II. Diseases in which dementia is associated with other neurologic signs but not with other obvious medical diseases
   A. Invariably associated with other neurologic signs
      1. Huntington chorea (choreoathetosis)
      2. Multiple sclerosis, Schilder disease, adrenal leukodystrophy, and related demyelinative diseases (spastic weakness, pseudobulbar palsy, blindness)
      3. Lipid-storage diseases (myoclonic seizures, blindness, spasticity, cerebellar ataxia)
      4. Myoclonic epilepsy (diffuse myoclonus, generalized seizures, cerebellar ataxia)
      5. Subacute spongiform encephalopathy; Creutzfeldt-Jakob disease; Gerstmann-Strausler-Scheinker disease (prion, myoclonic dementias)
      6. Cerebrocerebellar degeneration (cerebellar ataxia)
      7. Cerebrobasal ganglionic degenerations (apraxia-rigidity)
      8. Dementia with spastic paraplegia
      9. Progressive supranuclear palsy (falls, vertical gaze palsy)
     10. Parkinson disease
     11. Amyotrophic lateral sclerosis (ALS) and ALS-Parkinson-dementia complex
     12. Other rare hereditary metabolic diseases
   B. Often associated with other neurologic signs
      1. Multiple thrombotic or embolic cerebral infarctions andBinswanger disease
      2. Brain tumor (primary or metastatic) or abscess
      3. Brain trauma, such as cerebral contusions, midbrain hemorrhages, chronic subdural hematoma
      4. Lewy-body disease (parkinsonian features)
      5. Communicating, normal-pressure, or obstructive hydrocephalus (usually with ataxia of gait)
      6. Progressive multifocal leukoencephalitis
      7. Marchiafava-Bignami disease (often with apraxia and other frontal lobe signs)
      8. Granulomatous and other vasculitides of the brain
      9. Viral encephalitis (herpes simplex)

III. Diseases in which dementia is usually the only evidence of neurologic or medical diseases
    A. Alzheimer disease
    B. Pick disease
    C. Some cases of AIDS
    D. Progressive aphasia syndromes
    E. Frontotemporal and “frontal lobe” dementias associated with tau deposition, Alzheimer change, or with no specific pathologic alteration
    F. Degenerative disease of unspecified type

Note: The special clinical features and morbid anatomy of these many dementing diseases are discussed in appropriate chapters throughout this book, particularly Chap. 39 on degenerative disorders, Chaps. 37 and 41 on metabolic and nutritional disturbances, and Chap. 33 on chronic infections.
seem somewhat cumbersome and not based on newer genetic and molecular models. However, it is likely to be more useful to the student or physician not conversant with the many diseases that cause dementia.

**Differential Diagnosis**

Although confusion or dementia per se does not indicate a particular disease, certain combinations of symptoms and neurologic signs are more or less characteristic and may aid in diagnosis. The age of the patient, the mode of onset of the dementia, its clinical course and time span, the associated neurologic signs, and the accessible laboratory data constitute the basis of differential diagnosis. It must be admitted, however, that some of the rarer types of degenerative brain disease are at present recognized mainly by pathologic examination. The correct diagnosis of treatable forms of dementia—subdural hematoma, certain brain tumors, chronic drug intoxication, normal-pressure hydrocephalus, AIDS (reversible to some extent), neurosyphilis, cryptococcosis, pellagra, vitamin B12 and thiamine deficiency states, hypothyroidism, and other metabolic and endocrine disorders—is, of course, of greater practical importance than the diagnosis of the untreatable ones. Also important is the detection of a depressive illness, which may masquerade as dementia, and chronic intoxication with drugs or chemical agents, both of which are treatable.

The first task in dealing with this class of patients is to verify the presence of intellectual deterioration and personality change. *It may be necessary to examine the patient serially before one is confident of the clinical findings and their chronicity.* A mild aphasia from a focal brain lesion must not be mistaken for dementia. Aphasic patients appear uncertain of themselves, and their speech may be incoherent. Careful attention to the patient’s language performance will lead to the correct diagnosis in most instances. Further observation will disclose that the patient’s behavior, except that which is related to the language disorder, is not abnormal. Similarly, aside from certain dementing diseases that begin with prominent components of apraxia alone, an apractic disorder from a stroke should not be misinterpreted as dementia. It is a clinical truism that the abrupt onset of mental symptoms points to a delirium or other type of acute confusional state and occasionally to a stroke; inattention, perceptual disturbances, and often drowsiness are conjoined (Chap. 20). Also, progressive deafness or loss of sight in an elderly person may sometimes be misinterpreted as dementia.

There is always a tendency to assume that mental function is normal if a patient complains only of nervousness, fatigue, insomnia, or vague somatic symptoms and to label the patient as anxious. This will be avoided if one keeps in mind that a neurosis rarely has its onset in middle or late adult life. A practical rule is to assume that all mental illnesses beginning during this period are due either to structural disease of the brain or to depression.

Clues to the diagnosis of depression are the presence of frequent sighing, crying, loss of energy, psychomotor underactivity or its opposite, agitation with pacing, persecutory delusions, persistent hypochondriasis, and a history of depression in the past and in the family. Although depressed patients may complain of memory failure, scrutiny of their complaints will show that they can usually remember the details of their illness and that little or no qualitative change in other intellectual functions has taken place. Their difficulty is either a lack of energy and interest or preoccupation with personal worries and anxiety, which prevent the focusing of attention on anything except their own problems. Even during mental tests, their performance may be impaired by “emotional blocking,” in much the same way as the worried student blocks during an examination (“experiential confusion”). When such patients are calmed by reassurance and encouraged to try harder, their mental function improves, indicating that intellectual deterioration has not occurred. Conversely, it is helpful to remember that demented patients rarely have sufficient insight to complain of mental deterioration; if they admit to poor memory, they do so without conviction or full appreciation of the degree of their disability. The physician must not rely on the patient’s statements alone in gauging the efficiency of mental function and should seek corroboration from family members. Yet another problem is that of the impulsive, cantankerous, and quarrelsome patient who is a constant source of distress to employer and family. Such changes in personality and behavior (as, for example, in Huntington disease) may precede or mask early intellectual deterioration.

The neuropsychiatric symptoms associated with metabolic, endocrine, or toxic disorders (e.g., Cushing syndrome, vitamin B12 deficiency, hypercalcemia, uremia, etc.) may present difficulties in diagnosis because of the wide variety of clinical pictures by which they manifest themselves. Drowsiness or stupor and asterixis are the surest signs of a metabolic or drug-induced encephalopathy, but they are not always present. Psychosis with hallucinations and a great deal of fluctuation in behavior also bespeak an exogenously caused confusional state, with the exception that Lewy-body dementia also has these characteristics. Whenever any such metabolic or toxic disorder is suspected, a thorough review of the patient’s medications is crucial. Medications with atropinic activity, for example, can produce an apparent dementia or worsen a structurally based dementia, as discussed in Chap. 20. Occupational exposure to toxins and heavy metals should also be explored, but this is an infrequent cause of dementia; therefore slight or even moderately elevated levels of these chemicals in the blood should be interpreted cautiously. It is also useful to keep in mind that seizures are not a usual component of the degenerative dementias; when they are present, they generally do not appear until a very late stage.

Once it is decided that the patient suffers from a dementing condition, the next step is to determine by careful physical examination whether there are other neurologic signs or indications of a particular medical disease. This enables the physician to place the case in one of the three categories in the bedside classification (see above and Table 21-3). Ancillary examinations—such as CT, MRI, electroencephalography (EEG), lumbar puncture, measurement of blood urea nitrogen as well as serum concentrations of calcium and electrolytes, and finally liver function tests—should be carried out in most cases. The MRI and CT are of major importance in objectifying hydrocephalus, lobar atrophy, leukoencephalopathy, cerebrovascular disease, tumor, and subdural hematoma. Testing for syphilis, vitamin B12 deficiency, and thyroid function is also done almost as a matter of routine because the tests are simple and the dementias they cause are reversible. These are supplemented in individual circumstances by serologic testing for human immunodeficiency virus (HIV) infection, measurement of copper and ceruloplasmin levels (Wilson disease), heavy metal concentrations in urine or tissues, serum cortisol levels, and drug toxicology screening. The final step is to determine, from the total clinical picture, the particular disease within any one category.
MEMORY AND THE AMNESIC SYNDROME (KORSAKOFF SYNDROME; AMNESIC SYNDROME) (See also Chap. 41)

The terms listed above are used interchangeably to designate a unique disorder of cognitive function in which memory and learning are deranged out of proportion to all other components of mentation and behavior. The amnesic state, as originally defined by Ribot, possesses two salient features that may vary in severity but are always conjoined: (1) an impaired ability to recall events and other information that had been firmly established before the onset of the illness (retrograde amnesia) and (2) an impaired ability to acquire certain types of new information, i.e., to learn or to form new memories (anterograde amnesia). This dual aspect inspired one of Lewis Carroll’s characters to indicate that one’s memory works both ways, past and future (“It’s a poor sort of memory that works only backwards,” said the Red Queen). In other words, the functions of memory and learning are inseparable. A third invariable feature of the Korsakoff syndrome, contingent upon the retrograde amnesia, is an impaired temporal localization of past experience (see below, under “Confabulation”). Other cognitive functions (particularly the capacity for concentration, spatial organization, and visual and verbal abstraction), which depend little or not at all on memory, are usually impaired as well, but to a much lesser degree than memory function. The patient is usually lacking in initiative, spontaneity, and insight.

Equally important in the definition of the Korsakoff syndrome or amnesic state (these terms are preferable to Korsakoff psychosis) is the integrity of certain aspects of behavior and mental function. The patient must be awake, attentive, and responsive—capable of perceiving and understanding the written and spoken word, of making appropriate deductions from given premises, and of solving such problems as can be included within his forward memory span. These features are of particular diagnostic importance because they help to distinguish the Korsakoff amnesic state from a number of other disorders in which the basic defect is not in retenitive memory but in some other psychologic abnormality—e.g., an impairment in attention and perception (as in the delirious, confused, or stuporous patient), in recall (as in the hysterical patient), or in volition, i.e., the will to learn (as in the apathetic or abulic patient with frontal lobe disease or depression).

So-called short-term memory, as demonstrated by the ability to repeat a string of digits, is intact, but this is more a measure of attention and registration than of retenitive memory. Remote memory is relatively less affected than recent memory (Ribot’s rule, as discussed below).

Confabulation The creative falsification of memory in an alert, responsive individual is often included in the definition of the Korsakoff amnesic state but is not a requisite for diagnosis. It can be provoked by questions as to the patient’s recent activities. The replies may be recognized as partially remembered events and personal experiences that are inaccurately localized in the past and related with no regard to their proper temporal sequence. Whether one calls this a memory defect or confabulation is an academic matter. Far less frequent but more dramatic is a spontaneous recital of personal experiences, many of which are fantasies. These two forms of confabulation have been referred to as “momentary” and “fantastic,” respectively, and it has been claimed, on uncertain grounds, that the latter form reflects an associated lesion in the frontal lobes (Berlyne). In the patients with the alcoholic Korsakoff syndrome studied by M. Victor and R.D. Adams, so-called fantastic confabulation was observed mainly in the initial phase of the illness, in which it could be related to a state of profound general confusion; “momentary confabulation” came later, in the convalescent stage. In the chronic, stable stage of the illness, confabulation was rarely elicitable irrespective of how broadly this symptom was defined.

Neuropsychology of Memory It is noteworthy that memory function obeys certain neurologic laws. As memory fails, it first loses its hold on recent events. The extent in time of retrograde amnesia is proportionate to the magnitude of the underlying neurologic disorder. Early-life memories are better preserved and often have been integrated into habitual responses; nevertheless, with natural aging, there is also a gradual loss of early-life memories. In transitory amnesias (e.g., concussive head injury), memories are recovered in reverse order: first the remote and then the more recent. The enduring aspect of early-life memories in contrast to more recently experienced and learned material, a restatement of Ribot’s law, is apparent in both normal adults and in demented patients. As quoted by Kopelman, Ribot in 1882 stated “The progressive destruction of memory follows a logical order—a law . . . it begins at the most recent recollections which, being . . . rarely repeated and . . . having no permanent associations, represent organization in its feeblest form."

In the further analysis of the Korsakoff amnesic syndrome, it is necessary to consider the proposition that memory is not a unitary function but takes several forms. Thus, a patient with virtually no capacity to learn any newly presented information can still acquire some simple manual and pattern-analyzing skills (e.g., mirror reading). Moreover, having acquired these skills, the patient may have no memory of the circumstances in which they were acquired (implicit memory). The learning of simple mechanical skills has been referred to as procedural memory, in distinction to learning new data-based information, referred to as nonprocedural or declarative memory. Cohen and Squire have described this dichotomy as “knowing how” as opposed to “knowing that.” The comments on dementia in this chapter refer, of course, mainly to the declarative, informational type of memory. Loss of procedural skill is more in the realm of apraxia.

Much has also been written in the psychologic literature about two systems of memory referred to as episodic and semantic (Table 21-4). A pervasive problem with these terms is the lack of uniformity in defining them. To Tulving, whose writings on this subject are recommended, the term episodic denotes a memory system for dating personal experiences and their temporal relationships; semantic memory is one’s repository of perceptual and factual knowledge, which makes it possible to comprehend language and make inferences. This hardly constitutes a novel concept; Korsakoff himself clearly recognized that certain aspects of mental function (among them those now being defined as semantic memory) remain intact, despite the profound impairment of retenitive (episodic) memory. As confirmation of the separation of these two functions, Gadian and colleagues have described a group of five young patients who showed severe impairments of episodic memory with relative preservation of semantic memory, attributable to hypoxic-ischemic injury (bilateral hippocampal atrophy) sustained early in life. Here again, the subject matter most relevant to amnesia involves episodic, or autobiographical, memory.

Damasio has introduced yet another set of terms—generic
The full significance of these categorizations is still being explored. The categorical purity of semantic memory is open to question, as is the notion of a strict dichotomy between semantic and episodic memory. Most importantly, a separate anatomic basis for these systems of memory has not been clearly established (see below). Further interesting derivative issues regarding the neuropsychology of memory in relation to brain diseases can be found in the review by Kopelman. Among these is the degree to which a disparity between retrograde and anterograde memory can be detected in certain diseases that we cannot comment on from clinical experience. He also points out subtle distinctions between recall and memory by recognition.

Neuropsychologists have further subdivided memory and suggested that there are corresponding anatomic regions for specific categories (Table 21-4). Some of these more complex ones have been alluded to above and others are simply restatements of the act of registration. Furthermore, it is not surprising that the participation of certain areas of the brain not primarily involved in memory function, particularly the language and visuospatial areas, are required for the performance of certain memory tasks. However, the notion of a working memory has both clinical and neuropsychologic credibility. This term refers to a module of memory that registers the results of a mental operation and holds it temporarily in order to manipulate or use it to perform a subsequent operation; for example, serial arithmetic or alternating a series of letters and numbers. It is not clear how this relates to the capacity to register and attend to a task, but there is little question that this is a measurable form of memory. Several regions of the brain must be active during tasks of working memory, including the hippocampi and dorsal thalamus, but lesions of the dorsolateral prefrontal cortex most specifically impair the skill. The papers by Goldman-Rakic may be referred to for further discussion of the mechanisms that underlie working memory.

Finally, there are reasons, based mainly on the neuroanatomic and functional imaging studies discussed below, to view memory for spatial and topographic information in a particular way. Certainly the recollection of personally experienced events can be dissociated to some degree from the memory of the topographic arrangement of the scene in which these memories were formed, but often these two elements are inextricably bound in one experience. More salient may be a disproportionate degradation of learned topographic and directional information compared to learned semantic material; such a dissociation can be found, but only in relative terms, in patients who have injuries to their right hippocampus, whereas semantic material is dependent more on the left hippocampus (see below).

Anatomic Basis of the Amnesic Syndrome

Two anatomic structures are of central importance in memory function: the diencephalon (specifically the medial portions of the dorumedial and adjacent midline nuclei of the thalamus) and the hippocampal formations of the medial temporal lobes (dentate gyrus, hippocampus, parahippocampal gyrus, subiculum, and entorhinal cortex). Discrete bilateral lesions in these regions derange memory and learning out of all proportion to other cognitive functions, and even a unilateral lesion of these structures, especially of the dominant hemisphere, can produce a lesser degree of the same effect. The clinical-anatomic relationships that bear on this subject are discussed in greater detail by Aggleton and Saunders and in the monograph on Wernicke-Korsakoff syndrome by Victor, Adams, and Collins.

While central to memory function, these are not the only regions engaged in the formation and retrieval of memory, since a severe but less enduring defect in retentive memory has also been observed with damage of the septal gray matter; a cluster of midline nuclei at the base of the frontal lobes, just below the interventricular septum and including the septal nucleus, nucleus accumbens, diagonal band of Broca; and paraventricular hypothalamic gray matter (see the well-worked-out case of infarction of this region reported by Phillips and colleagues). These septal nuclei have connections with the hippocampus through the precommissural fornix and with the amygdala through the diagonal band. The amnesic syndrome that follows ruptured anterior communicating aneurysm is due to disruption of these nuclei. Again, what is most remarkable about this basal frontal amnesic syndrome is its initial severity lasting for weeks to months and the potential for almost complete recovery.

Experimental studies in monkeys have confirmed the importance of the diencephalic-hippocampal structures in memory function. (The reviews of these studies by Zola-Morgan et al are recommended.) The difficulty of evaluating memory function in monkeys has been largely overcome by use of the delayed non-matching-to-sample task, which is essentially a refined test of recognition memory and is impaired in both patients with the amnesic syndrome and in monkeys with lesions of the mediadorsal nuclei of the thalamus and inferomedial temporal cortical regions (Mishkin and Delacour). Using this method and several others that simulate a restricted form of human amnesia, Zola-Morgan and colleagues have shown that bilateral lesions of the hippocampal formation cause an enduring impairment of memory function. Lesions confined to the fornices or mammillary bodies and stereotaxic lesions of the amygdala that spared the adjacent cortical regions (entorhinal and perirhinal cortices) failed to produce a memory defect. However, lesions that were confined to the perirhinal and entorhinal cortex (Brodmann’s areas 35 and 36) and the closely associated parahippocampal cortex did cause a persistent memory defect, presumably by interrupting the major afferent pathways conveying cortical information to the hippocampus. Lesions of the anteromedial parts of the diencephalon, which receive and send fibers to the amygdala and hippocampus, similarly abolished memory function.

A body of modern work using functional neuroimaging also addresses the anatomic representation of memory function. It is found that the hippocampal formations are consistently engaged during memory acquisition and retrieval tasks, confirming the fundamental role of these structures. Furthermore, as alluded to earlier, Maguire’s group has found a differential activation of the right side during recall of topographic spatial information and the left side for autobiographical memory. Their clever use of London taxi drivers as subjects for imaging studies has further suggested that the volume of the right hippocampus is larger in subjects who have more experience navigating the arcane streets of London (Maguire et al). This asymmetric representation of certain modalities of memory is in keeping with limited clinicopathologic studies of patients who have undergone temporal lobectomy on one side.

These observations in aggregate indicate that integrity of the hippocampal formations and the mediodorsal nuclei of the thalamus are essential for normal memory and learning. Interestingly, there are only sparse direct anatomic connections between these two regions. The importance assigned to the hippocampal formations and medial thalamic nuclei in memory function does not mean that the mechanisms governing this function are confined to these structures or that these parts of the brain form a “memory center.” It informs us only that these are the sites where the smallest lesions have the most devastating effects on memory and learning. Normal memory function, as emphasized, involves many parts of the brain in addition to diencephalic-hippocampal structures. The aforementioned basal frontal nuclei that project to the hippocampi are an example. It is also clear that extensive lesions of the neocortex may cause impairment of retentive memory and learning and that this effect is probably more dependent upon the size of the lesion than upon its locus. Of particular importance are the circumscribed areas of the cerebral cortex related to special forms of learning and memory (so-called modality-based memory), a subject that is considered in detail in the next chapter. Thus, a lesion of the dominant temporal lobe impairs the ability to remember words (loss of explicit semantic memory), and a lesion of the inferior parietal lobule undermines the recognition of written or printed words as well as the ability to relearn them (alexia). The dominant parietal lobe is related to recollection of geometric figures and numbers; the nondominant parietal lobe, to visuospatial relations; the inferoposterior temporal lobes, to the recognition of faces; and the dominant posterofrontal region, to acquiring and remembering motor skills and their affective associations. Whether these are truly forms of memory or whether these regions of cortex must be entrained in order to retrieve and “experience” the memory is semantic. Taken to its extremes, aphasia from a left temporal perisylvian lesion (Wernicke aphasia) could be viewed as an amnesia for language, and parietal lesions that cause ideomotor apraxia could be taken to represent a loss of memory for these previously learned acts. What remains clear is that the integrity of both the hippocampal-thalamic system and the appropriate cortical region is required for memory as it is commonly understood, but only the former is integrated into all modalities of learning and retrieval.

Any hypothesis concerning the anatomic substratum of learning and retentive memory must therefore include not only the diencephalic-hippocampal structures but also special parts of the neocortex and midbrain reticular formation (for maintaining alertness). We would suggest that the diencephalic-hippocampal structures are involved in all active phases of learning and integration of new information, regardless of the sense avenue through which this information reaches the organism or of the final pathway of its expression, and it seems to make little difference whether the newly acquired information involves functions classified as purely cognitive or as emotional. It is a remarkable feature of the Korsakoff amnestic state that no matter how severe the defect in retentive memory may be, it is never complete. Certain past memories can be recalled, but...
IV. Slowly progressive amnesic states

Also unknown are the anatomic and physiologic mechanisms that govern immediate registration, which remains intact in even the most severely damaged patients with the Korsakoff amnesic syndrome. Equally obscure are the anatomic arrangements that enable the patient with virtually no capacity to retain any newly presented factual information to still learn some simple perceptual-motor and cognitive skills, even though there may be no memory of having been taught these skills in the first place. Other psychologic features of human memory that must be accounted for by any model purporting to explain this function are the importance of cueing in eliciting learned material and the imprecision of past memories, allowing for unwitting embellishment and false recollection, to the point of fabrication. The latter aspect has been a topic of considerable importance in children who have (or have not) been subjected to sexual abuse and in adults and children whose memories of past abuse have been suggested by the examiners (see Schacter).

Also of interest are the separate roles of the thalamus, the hippocampi, and the frontal lobes in memory and whether the nature of the amnesia resulting from damage at one site differs from the others. That isolated thalamic lesions, without implicating medial temporal areas, can cause a Korsakoff syndrome is evident from the experience with alcoholism. Graff-Radford and colleagues have found that with purely thalamic lesions, as appreciated by imaging studies, anterograde learning is more affected than retrograde recall; but comparing these functions quantitatively seems to us quite difficult. Kopelman, in reviewing his own studies and those of others, concludes that the differences are subtle and pertain mostly to temporal ordering and the modality of information, which is degraded more with diencephalic-temporal lesions than with frontal lobe damage.

The cellular mechanisms involved in learning and the formation of memories are only beginning to be understood. Whether physiologic phenomena such as long-term potentiation or anatomic changes in the dendritic structure of neurons are at the center of memory storage is not known; certainly both are likely to be involved. The neurochemical systems that are activated during formation and recall of memory are also obscure. Kandel has provided a detailed review of information on this subject (see the References).

Classification of Diseases Characterized by an Amnesic Syndrome

The amnesic (Korsakoff) syndrome may be a manifestation of several neurologic disorders, identified by their mode of onset and clinical course, the associated neurologic signs, and ancillary findings (Table 21-5). Each of the amnesic states listed in Table 21-5 is considered at an appropriate point in subsequent chapters of this book. The only exception is the striking syndrome of transient global amnesia, the nature of which is not certain. It cannot be included with any assurance with the epilepsies or the cerebrovascular diseases or any other category of disease and is therefore considered here.

Transient Global Amnesia

This was the name applied by Fisher and Adams to a particular type of memory disorder that they observed in more than 20 middle-aged and elderly persons. The condition was characterized by an episode of amnesia and bewilderment lasting for several hours. The symptoms had their basis in an amnesia for events of the
A large number of patients have been studied with EEGs during suggested that it represents an unusual form of temporal lobe epilepsy differentiating the attack from a partial complex seizure. Unlike those with psychomotor epilepsy, the patient is alert, in contact with his surroundings, and capable of high-level intellectual activity and language function during the attack. As soon as the attack has ended, no abnormality of mental function is apparent except for a permanent gap in memory for the period of the attack itself and for a brief period (hours or days) preceding the attack. The patient may be left with a mild headache. Incomplete or mild attacks are not seen. Only the recent retrograde and complete anterograde amnesia stand out. The condition is among the most curious in neurology but is often mistaken for a psychiatric episode.

Hodges and Ward have made detailed psychologic observations in five patients during an episode. The psychologic deficit, except for its transience, was much the same as that in the permanent amnesia syndrome. Personality, cognition involving high-level functioning, semantic language, and visuospatial discrimination were all preserved. So-called immediate memory—i.e., registration (see above)—was intact, but retentive memory was severely deranged. The extent of retrograde amnesia was highly variable, but characteristically it shrank after the attack, leaving a permanent retrograde gap of about 1 h. However, some mild impairment of new learning persisted for up to a week after the acute attack.

In a survey conducted in the Rochester, Minnesota, area, transient global amnesia (TGA) occurred at an annual rate of 5.2 cases per 100,000 population. The recurrence of such attacks is not uncommon, having been noted in 66 of 277 patients who were observed for an average period of 80 months (Miller et al) and in 16 of 74 patients followed for 7 to 210 months (Hinge et al). The latter authors estimate the mean annual recurrence rate to be so low (4.7 percent) that most elderly patients are likely to experience only one attack. One of our patients had more than 50 attacks, but among all the rest (more than 100 cases), 5 was the maximum. It seems children are not susceptible to the condition; however, a 13-year-old and 16-year-old with migraine were reported to have had similar attacks during participation in sports (Tosi and Righetti).

No consistent antecedent events have been identified, but certain ones—such as a highly emotional experience, pain, exposure to cold water, sexual intercourse, and mild head trauma—have been reported in some cases (Haas and Ross; Fisher). The similarity to postconcussive amnesia is notable. We have also seen several patients in whom the attacks appeared after minor diagnostic procedures such as colonoscopy, but the residual effects of sedation are suspect in some of these instances. Several cases have been reported in high-altitude climbers and created difficulty in distinguishing TGA from altitude sickness. One of the difficulties in judging the accuracy of the many published reports is whether, during the attack, the patient was or was not in contact with the environment and capable of high-level mental performance and whether a retrograde amnesia was present—important features in differentiating the attack from a partial complex seizure.

The pathogenesis of TGA has not been settled. It has been suggested that it represents an unusual form of temporal lobe epilepsy (transient epileptic amnesia, TEA), but this seems unlikely. A large number of patients have been studied with EEGs during an attack or shortly thereafter and have not shown seizure activity (Miller et al). Moreover, amnesic episodes due to seizures are usually much briefer than those of TGA, and most or all temporal lobe seizures are associated with impairment of consciousness and an inability to interact fully with the social and physical environment. Using EEG and nasopharyngeal leads, Rowan and Protass found mesiotemporal spike discharges in 5 of 7 patients. Curiously, they attributed the discharges to ischemic lesions during drug-induced sleep, making the observations ambiguous. Palmini and coworkers cite exceptional cases of pure amnesic seizures in temporal lobe epilepsy, but even in their best examples, ictal and postictal function was not normal.

More likely in our view, transient global amnesia is ischemic or perhaps migrainous in nature, though not atherothrombotic. Rarely (if ever) do the attacks progress to stroke. Regarding cerebrovascular disease and TGA, Hinge and associates and Hodges and Warlow, in a case-control study of 114 patients with transient global amnesia, found no evidence of an association with cerebrovascular disease; there was, however, a significantly increased history of migraine, as there was in the series of Miller and coworkers (14 percent) and of Caplan and colleagues. From indirect evidence of retrograde blood flow in the internal jugular arteries during the Valsalva maneuver (occasionally reported to precipitate an attack), Sander and colleagues suggested that venous congestion of the temporal lobes was operative. The most compelling cases for an ischemic basis of TGA, perhaps most relevant to migraine, comes from Stillhard and colleagues, who demonstrated bitemporal hypoperfusion during an attack of TGA, and from Strupp et al and Sedlaczek and others, who have demonstrated left mediotemporal changes (interpreted as cellular edema) with diffusion-weighted MRI. In the study by the latter authors, signal changes in the hippocampi were delayed for 48 h. The precipitation of identical attacks by vertebrobasilar and coronary angiography is also suggestive of an ischemic or migrainous causation.

The benignity of episodic global amnesia in most patients is noteworthy. Once the history and examination have excluded vertebrobasilar ischemia and temporal lobe epilepsy, no treatment is required other than an explanation of the nature of the attack and reassurance, although we often hospitalize such patients briefly to be certain that the episode clears without further incident. The diagnosis should not be accepted if there has been ataxia, vertigo, diplopia, or other visual complaints, or if there are deficits in cognition that extend beyond the limited retrograde and complete anterograde amnesia.

**APPROACH TO THE PATIENT WITH DEMENTIA AND THE AMNESIC STATE**

The physician presented with a patient suffering from dementia and amnesia must adopt an examination technique designed to expose the intellectual defect fully. Abnormalities of posture, movement, sensation, and reflexes cannot be relied on to disclose the disease process. Suspicion of a dementing disease is aroused when the patient presents multiple complaints that seem totally unrelated to one another and to any known syndrome; when symptoms of irritability, nervousness, and anxiety are vaguely described and do not fit exactly into one of the major psychiatric syndromes; and when the patient is incoherent in describing the illness and the reasons for consulting a physician.
Three categories of data are required for the recognition and differential diagnosis of dementing brain disease:

1. A reliable history of the illness
2. Findings on mental examination, i.e., the mental status as well as on the rest of the neurologic examination
3. Ancillary examinations: CT, MRI, sometimes lumbar puncture, EEG, and appropriate laboratory procedures, as described in Chap. 2

The history should generally be supplemented by information obtained from a person other than the patient, because, through lack of insight, the patient will have no grasp of his illness or its gravity; indeed, he may be ignorant even of his chief complaint. Special inquiry should be made about the patient’s general behavior, capacity for work, personality changes, language, mood, special preoccupations and concerns, delusional ideas, hallucinatory experiences, personal habits and care in hygiene, and such faculties as memory and judgment.

The examination of the mental status should be systematic and include some of the following general categories with suggested examples for testing as modified for each patient’s circumstances:

1. **Insight** (patient’s replies to questions about the chief symptoms): What is your difficulty? Are you ill? When did your illness begin?
2. **Orientation** (knowledge of personal identity and present situation): What is your name, address, telephone number? What is your occupation? Are you married?
   a. **Place**: What is the name of the place where you are now (building, city, state)? How did you get here? What floor is it on? Where is the bathroom?
   b. **Time**: What is the date today (day of week and of month, month, year)? What time of the day is it? What meals have you had? When was the last holiday?
3. **Memory**.
   a. **Remote**: Tell me the names of your children (or grandchildren) and their birth dates. When were you married? What was your mother’s maiden name? What was the name of your first schoolteacher? What jobs have you held? We also find it useful to quiz the patient about cultural icons of the past that are appropriate to his age. Most patients should be able to name the presidents in reverse order dating to their twenties.
   b. **Recent past**: Tell me about your recent illness (compare with previous statements). What is my name (or the nurse’s name)? When did you see me for the first time? What tests were done yesterday? What were the headlines of the newspaper today?
   c. **Immediate recall**—(attention and “short-term memory”): Repeat these numbers after me (give series of 3, 4, 5, 6, 7, 8 digits at a speed of one per second). Now when I give a series of numbers, repeat them in reverse order.
   d. **Memorization** (learning): The patient is given three or four simple data (examiner’s name, date, time of day, and a fruit, structure, or trait, such as honesty—we use “a red ball, Beacon Street, and an envelope”) and is asked to repeat them after a minute or a brief story containing several facts and is asked to recount the main facts as soon as the story is over. The capacity to reproduce them at intervals after committing them to memory is a test of **retentive memory span**.
   e. Another test of memory and verbal fluency we have found useful is the generation of a list of objects in a category; ask the patient to give the names of animals, vegetables, or makes of cars, as many as come to mind in 30 s or so; most individuals can list at least 12 items in each category.
   f. **Visual span**: Show the patient a picture of several objects; then ask him to name the objects.
4. **Capacity for attention and working memory**: Crossing out all the a’s on a printed page; counting forward and backward; saying the months of the year forward and backward; spelling **world** forward and then backward. Verbal trail making (reciting alternating letters of the alphabet and their ordinal place i.e., A-1, B-2, C-3, D- . . .)
   a. **Calculation**: Test ability to add, subtract, multiply, and divide. Subtraction of serial 3’s and 7’s from 100 is a good test of calculation as well as of concentration.
   b. **Constructions**: Ask the patient to draw a clock and place the hands at 7:45, a map of the United States, a floor plan of her house; ask the patient to copy a cube and other figures.
   c. **Abstract thinking**: See if the patient can describe the similarities and differences between classes of objects (orange and apple, horse and dog, desk and bookcase, newspaper and radio) or explain a proverb or fable (“People who live in glass houses shouldn’t throw stones”; “A stitch in time saves nine”; “A rolling stone gathers no moss”; “Idle hands are the devil’s workshop”).
5. **General behavior**: Attitudes, general bearing, evidence of hallucinosis, stream of coherent thought and attentiveness (ability to maintain a sequence of mental operations), mood, manner of dress, etc.
6. **Special tests of localized cerebral functions**: Grasping, sucking, aphasia battery, praxis with both hands, and corticosenory function.

In order to enlist the full cooperation of the patient, the physician must prepare him for questions of this type. Otherwise, the patient’s first reaction will be one of embarrassment or anger because of the implication that his mind is unsound. It should be pointed out to the patient that some individuals are rather forgetful or have difficulty in concentrating, or that it is necessary to ask specific questions in order to form some impression about his degree of nervousness when being examined. Reassurance that these are not tests of intelligence or of sanity is helpful. If the patient is extremely agitated, suspicious, or belligerent, intellectual functions must be inferred from his remarks and from information supplied by the family.

This type of mental status survey can be accomplished in about 10 min. In our experience, a high level of performance on all tests eliminates the possibility of dementia in 95 percent of cases. It may fail to identify a dementing disease in an uncooperative patient and in a highly intelligent individual in the earliest stages of disease.

The question of whether to resort to formal psychologic tests is certain to arise. Such tests yield quantitative data of comparative value but cannot of themselves be used for diagnostic purposes.

Scoring  
A score of 24 or above is considered normal. 30

The Mini-Mental Status examination of Folstein and coworkers and the Short Test of Mental Status of Kokmen and colleagues are useful bedside methods of scoring cognitive impairment and following its progress (Table 21-6). A score of 24 on the widely used “mini-mental” is considered normal and scores below 21 generally indicate cognitive impairment. Patients with lower levels of education and older age have lower normative scores, but even individuals in their eighties with a high school education score 23 or above if not demented. A number of other tests that measure the degree of dementia (Roth, Pfeiffer, Blessed, Mattis) rely essentially on the points mentioned above and a brief assessment of the patient’s ability to accomplish the activities of daily living, which is lost in the later stages of disease. Probably the Wechsler Adult Intelligence Scale (WAIS) is the most accurate. In this test, an index of deterioration is provided by the discrepancy between the vocabulary, picture-completion, and object-assembly tests as a group (these correlate well with premorbid intelligence and are relatively insensitive to dementia brain disease) and other measures of general performance, namely arithmetic, block-design, digit-span, and digit-symbol tests. The Wechsler Memory Scale estimates the degree of memory failure and can be used to distinguish the amnesic state from a more general dementia (discrepancy of more than 25 points between the WAIS and the memory scale). Questions that measure spatial and temporal orientation and retentive memory are the key items in most of these abbreviated scales of dementia. All of the aforementioned clinical and psychologic tests, and several others as well, measure the same aspects of behavioral and intellectual function. The WAIS and the Mini-Mental Status examination of Folstein and associates are the most widely used clinically.

Management of the Demented Patient

Dementia is a clinical state of the most serious nature. Though now sometimes impractical, it is usually worthwhile to admit such patients to the hospital for a period of observation. Alternatively, the physician can see the patient serially over a period of weeks, during which the appropriate laboratory tests (blood, cerebrospinal fluid analysis, and CT or MRI) can be carried out. The management of demented patients in the hospital may be relatively simple if they are quiet and cooperative. If the disorder of mental function is severe, it is helpful if a nurse, attendant, or member of the family can stay with the patient at all times.

The primary responsibility of the physician is to diagnose the treatable forms of dementia and to institute appropriate methods of therapy. Once it is established that the patient has an untreatable dementing brain disease and the diagnosis is sufficiently certain, a responsible member of the family should be informed of the medical facts and prognosis and assisted in the initiation of social and support services. Patients themselves need be told only that they have a nervous condition for which they are to be given rest and support services. Patients themselves need be told only that they have a nervous condition for which they are to be given rest and treatment. Some physicians (and patients) find this too patronizing; certainly, in the current social environment, many patients ask directly if they have Alzheimer disease. To this query we respond that they may, but that more time is required to be certain. Some intelligent patients have insisted on knowing the details and implications of this statement, and we have felt obliged to give as much useful information as required by them; but little is accomplished by telling them more. Reassurance that the physician will be available to help the patient and family manage the situation is of utmost value. Crises should be pre-empted by regular contact with a physician. If the dementia is slight and circumstances are
Questions asked by the patient’s family must be answered patiently and sensitively by the physician. Common questions are “Should I correct or argue with the patient?” (No.) “Can the patient be left alone?” “Must I be there constantly?” (Depends on specific circumstances and the severity of dementia.) “Should the patient manage his own money?” (Generally not.) “Will a change of environment or a trip help?” (Generally not—often the disruption in daily routine worsens behavior and orientation.) “Can she drive?” (Best to advise against driving in most instances.) “What shall we do about the patient’s fears at night and his hallucinations?” (Medication under supervision may help.) “When is a nursing home appropriate?” “How will the condition worsen? What should the family expect, and when?” (Uncertain, but usually a 5- to 10-year course.) Many families have found the information on the Alzheimer Association website, www.Alz.org, helpful, but physician guidance is required to make the comments applicable to individual circumstances.

Visiting nurses, social agencies, live-in health-care aides, day care settings, and respite care to relieve families from the constant burden of caring for the patient should all be used to advantage. Some of the inevitable practical problems accompanying the dissolution of personal life caused by dementia can be ameliorated by judicious use of powers of attorney or guardianship and similar legal vehicles.

The age-old controversy about cerebral functions—whether they are diffusely represented in the cerebrum, with all parts roughly equivalent, or localized to certain lobes or regions—was resolved long ago. Clinicians and physiologists have demonstrated beyond doubt that particular functions are assignable to certain cortical regions. For example, the pre- and postrolandic zones control motor and sensory activities, the striate-parastriate occipital zones control visual, the superior temporal and transverse gyri of Heschl are auditory, and so on. Beyond these broad correlations, however, there is a notable lack of precision in the cortical localization of many of the behavioral and mental operations described in Chaps. 20 and 21. In particular, of the higher-order physiologic and psychologic functions—such as attention, vigilance, apperception, thinking, etc.—virtually none has a precise and predictable anatomy; or, more accurately, the neural systems on which they depend are widely distributed among several regions.

One may suitably pause and inquire into what precisely is meant by cerebral localization. Does it refer to the physiologic function of a circumscribed aggregate of neurons in the cerebral cortex, indicated clinically by a loss of that function (negative symptom) when the neurons in question are paralyzed or destroyed? From what we know of the rich connectivity of all parts of the so-called cortical centers, one must assume that this is only partly the case, in that a lesion in a particular cerebral region, or in the fiber systems with which it is connected, is most closely associated with certain impairments of function. While it is appropriate for the clinician to operate on the principle of correlation between certain neurologic signs or syndromes and damage (lesion) in particular regions of the brain, it is readily apparent that certain positive symptoms resulting from the lesion—e.g., the grasping and sucking responses—cannot arise from destroyed neurons but are attributable to the now altered or disinhibited functions of closely related intact parts of the cerebrum. And how is one to interpret the seeming inconsistencies from one case report to another, in which several different functions have been assigned to the same region of the brain and any one region appears to be the anatomic substratum of multiple functions or in which a particular sign arises from damage in one of several areas? Most modern theorists who ponder this subject believe that the organization of cerebral function is based on discrete networks of closely interconnected afferent and efferent neurons in several regions of the brain. These networks must be linked by both regional and more widespread systems of fibers. This is especially apparent in the discussion of the anatomy of complex cognitive properties such as intelligence, as described in Chap. 21.

Most of these aspects of cerebral localization—brought so clearly in the writings of Wernicke, Déjerine, and Liepmann—have been elaborated by the Russian school of physiologists and psychologists and resurrected more recently by Geschwind. They viewed function not as the direct property of a particular, highly specialized group of cells in one region of the cerebrum but as the product of complex, diffusely distributed activity by which sensory stimuli are analyzed and integrated at various levels of the nervous system and are united, through a system of temporarily acquired (experimentally derived) connections, into a working mosaic adapted to accomplish a particular task. To some extent, this model has been corroborated by functional imaging studies, which show increased metabolic activity in several cortical regions during every form of human behavior, including willed motor acts, language tasks, and perceptive and apperceptive sensory experiences. Within such a functional system, the initial and final links (the task and the effect) remain unchanged, but the intermediate links (the means of performance of a given task) may be modified within wide limits and will never be exactly the same on two consecutive occasions. Thus, when a certain act is called for by a spoken command, the dominant temporal lobe must receive the message and transmit it to the premotor areas. Or it may be initiated by the intention of the individual, in which case the first measurable cerebral activity (a negative “readiness potential”) occurs anterior to the premotor cortex. The motor cortex is also always under the dynamic control of the proprioceptive, visual, and vestibular systems. Loss of a skilled act may therefore be caused by a lesion that affects any one of several elements in the act, either the motor centers themselves or their connections with the other elements.

It is important to again point out that this concept of cerebral function and localization, which applies to all mental activities, contradicts both the concept that postulates a functional equivalence of all cerebral regions and also the one that assumes strict localization of any given activity within one part of the brain. This centrist view has been, in our view, largely confirmed by neuropsychologic analysis, which has been the approach of A. R. Luria and others of the Russian school and by behavioral psychologists of the Skinner school. It is also supported by modern neuroimaging studies, which demonstrate the activation of several cortical regions by almost any task, as discussed below.

Another theoretical scheme of cerebral anatomy and function systematizes cortices of similar overall structure and divides the cerebral mantle into three longitudinally oriented zones. A central vegetative neuronal system (allocortex and hypothalamus) provides the mechanisms for all internal functions—the milieu intérieur of Bernard and Cannon. An outer zone, comprising the sensorimotor and association cortices and their projections, provides the mechanisms for perceiving the external world and interacting with it and a region between them (limbic-paralimbic cortices) that provides
the bridges that permit the adaptation of organismal needs to the external environment. This concept of central nervous system function, first proposed by Broca, was elaborated by Yakovlev and has been adopted more recently by Mesulam and by Benson. Such a model retains to a large degree the cytoarchitectural similarities among areas that serve similar functions (i.e., the scheme of Brodmann) and also respects the sequence of maturation (myelination) of connecting pathways proposed by Flechsig (see Fig. 28-3). The latter corresponds to the functional development of primary, secondary, and tertiary associative cortical regions. In this way, localization may be viewed as the product of genetic patterns of structure, which mature during development, and their synaptic formations, which permit the development of complex circuits during lifelong learning and experience.

From these remarks it follows that subdivision of the cerebrum into frontal, temporal, parietal, and occipital lobes is somewhat of an anachronism of limited psychophysiological validity, although, in clinical work, it still serves an important practical purpose as a shorthand way of localizing a lesion. Some of these delineations were made long before our first glimmer of knowledge about the function of the cerebrum. Even when the neurohistologists began parceling the neocortex, they found that their areas did not fall neatly within zones bounded by sulci and fissures. Therefore, when the terms frontal, parietal, temporal, and occipital are used in the text below, it is mainly to provide the clinician with familiar and manageable anatomic landmarks (see Fig. 22-7).

Following from the issues expressed above, a comment should be made regarding the study of cortical function by functional imaging techniques [positron emission tomography (PET) and functional magnetic resonance imaging (fMRI)]. These extraordinary images reveal the brain regions that are activated during various normal behaviors. Some techniques use regional cerebral blood flow, regional oxygen content, or diffusion of water as surrogates for local metabolic brain activity and neuronal activation (see reviews by Gore and by Le Bihan). Invariably, an ensemble of areas, a “network” of the variety mentioned above, is required to perform even seemingly simple tasks such as recalling a name, visualizing or identifying an object, or carrying out a commanded task. The fact that multiple areas of the cortex are entrained may seem at odds with the classic view of lesional neurology in which one localized area is assigned to a particular clinical syndrome (as defined by a behavioral deficit). The discrepancy is in part one of epistemology in that normal function as reflected in functional images does not equate with abnormal function as exposed by a focal lesion. Moreover, it appears from these imaging studies that certain regions of the cortex are necessary to fully conduct particular behaviors, but they are not sufficient for their enactment. Restated, a number of ancillary regions appear by functional imaging to participate in these behaviors, but they act in a supplementary way. A rough analogy can be made with memory function as described in Chap. 21, where hippocampal destruction results in complete amnesia but undeniably other areas of the brain participate in normal memory. Possibly lesions in these supplementary areas may impair function to a small degree, but these areas are not requisite for the behavior and therefore are not demonstrable in the clinical examination. These considerations notwithstanding, there is little doubt that functional imaging provides insights into the co-ordinated interaction of spatially distributed brain regions in normal behavior. They also promise to illuminate patterns of diseased brain function and recovery from these processes.

### General Anatomic and Physiologic Considerations of Cortical Function

Pertinent to this subject are a number of morphologic and physiologic observations. Along strictly histologic lines, Brodmann distinguished 47 different areas of cerebral cortex (Fig. 22-1), and von Economo identified more than twice that number. Although this parceling was criticized by Bailey and von Bonin, it is still used by physiologists and clinicians, who find that the Brodmann’s areas do indeed approximate certain functional zones of the cerebral cortex (Fig. 22-2). Also, the cortex has been shown to differ in its various parts by virtue of its particular connections with other areas of the cortex and with the thalamic nuclei and other lower centers. Hence, one must regard the cortex as a heterogeneous array of many anatomic systems, each with highly organized intercortical and diencephalic connections.

Certain general aspects of cerebrocortical anatomy are particularly noteworthy. The sheer size of the cortex is remarkable. Unfolded, it has a surface extent of about 4000 cm²—about the size of a full sheet of newsprint (right and left pages). Contained in the cortex are many billions of neurons (estimated at 10 to 30 billion) and five times this number of supporting glial cells. The intercellular synaptic connections number in the trillions. Since nerve cells look alike and presumably function alike, the remarkable diversity in human intelligence, store of knowledge, and behavior must depend on the potential for infinite variations in neuronal interconnectivity.

Most of the human cerebral cortex is phylogenetically recent, hence the term neocortex. It has also been referred to as isocortex (Vogt) because of its uniform embryogenesis and morphology. These latter features distinguish the neocortex from the older and less uniform allocortex (“other cortex”), which comprises mainly the hippocampus and olfactory cortex. Concerning the detailed histology of the neocortex, six layers (laminae) can be distinguished; from the pial surface to the underlying white matter they are as follows: the molecular (or plexiform), external granular, external pyramidal, internal granular, ganglionic (or internal pyramidal), and multiform (or fusiform) layers, as illustrated in Fig. 22-3. Two cell types—relatively large pyramidal cells and smaller, more numerous rounded (granular) cells—predominate, and variations in the lamination of the neocortex are largely determined by variations in the size and density of these neuronal types. Many variations in lamination have been described by cortical mapmakers, but two main types of neocortex are recognized: (1) the homotypical cortex, in which the six-layered arrangement is readily discerned, and (2) the heterotypical cortex, in which the layers are less distinct. The association cortex—the large areas (75 percent of the surface) that are not obviously committed to primary motor or sensory functions—is generally of this latter type. Homotypical areas are characterized by either granular or agranular nerve cells. The precentral cortex (Brodmann’s areas 4 and 6, mainly motor region) is dominated by pyramidal rather than granular cells, especially in layer V (hence the term agranular). Agranular cortex is distinguished by a high density of large pyramidal neurons. In contrast, primary sensory cortex—postcentral gyrus (areas 3, 1, 2), banks of the calcarine sulcus (area 17), and the transverse gyri of Heschl (areas 41 and 42)—where layers II and IV are strongly developed for the receipt of afferent impulses, has been termed granular cortex because of the marked predominance of granular cells. Granular cortex has a preponderance of small neurons (Fig. 22-4).
Beyond these morphologic distinctions, the intrinsic organization of the neocortex follows a pattern elucidated by Lorente de Nó. He described vertical chains of neurons that are arranged in cylindrical modules or columns, each containing 100 to 300 neurons and heavily interconnected up and down between cortical layers and to a lesser extent horizontally. Figure 22-5 illustrates the fundamental vertical (columnar) organization of these neuronal systems. Afferent fibers activated by various sensory stimuli terminate mainly in layers II and IV. Their impulses are then transmitted by intermuncial neurons (interneurons) to adjacent superficial and deep layers and then to appropriate efferent neurons in layer V. Neurons of lamina III (association efferents) send axons to other parts of the association cortex in the same and opposite hemisphere. Neurons of layer V (projection efferents) send axons to subcortical structures and the spinal cord. Neurons of layer VI project mainly to the thalamus. In the macaque brain, each pyramidal neuron in layer V has about 60,000 synapses, and one afferent axon may synapse with dendrites of as many as 5000 neurons; these figures convey some idea of the wealth and complexity of cortical connections. These columnar ensembles of neurons, on both the sensory and motor sides, function as the elementary working units of the cortex, in a manner that is most apparent in the motor and sensory activities described in Chaps. 3, 8, and 9.

Whereas certain regions of the cerebrum are committed to special perceptual, motor, sensory, mnemonic, and linguistic activities, the underlying intricacy of the anatomy and psychophysical

mechanisms in each region are just beginning to be envisioned. The lateral geniculate-occipital organization in relation to vision and recognition of form, stemming from the work of Hubel and Wiesel, may be taken as an example. In area 17, the polar region of the occipital lobe, there are discrete, highly specialized groups of neurons, each of which is activated in a small area of lamina 4 by spots of light or lines and transmitted via particular cells in the lateral geniculate bodies; other groups of adjacent cortical neurons are essential for the perception of color (see also page 404). Preparedness for all types of visual stimulation and recognition of objects, faces, and verbal and mathematical symbols also involves these areas but is integrated with other cortical regions. Lying between the main uni-modal receptive areas for vision, audition, and somesthetic perception are zones of integration called heteromodal cortices. In the latter regions, neurons respond to more than one sensory modality or neurons responsive to one sense are interspersed with neurons responsive to another.

Cortical-subcortical integrations are reflected in volitional or commanded movements. A simple movement of the hand, for example, requires activation of the premotor cortex (also called accessory motor cortex), which projects to the striatum and cerebellum and back to the motor cortex via a complex thalamic circuitry before the direct and indirect corticospinal pathways can activate certain combinations of spinal motor neurons (see Chaps. 3 and 4).

Interregional connections of the cerebrum are required for all natural sensorimotor functions; moreover, as indicated above, their destruction disinhibits or “releases” other areas. Denny-Brown has referred to the latter as cortical tropisms. Or, the cortical areas surrounding a particular region may be damaged and result in a unique deficit that is the result of isolation or disconnection of that region. Thus, destruction of the premotor areas, leaving precentral and parietal lobes intact, results in release of sensorimotor automatisms such as groping, grasping, and sucking. Parietal lesions result in complex avoidance movements to contactual stimuli. Temporal lesions lead to a visually activated reaction to every observed object and its oral exploration, and limbic sexual mechanisms are rendered hyperactive.

Some of the aforementioned disorders and others known simplistically as disconnection syndromes depend not merely on involvement of certain cortical regions but also on the interruption of inter- and intra-
hemispheric fiber tracts. Some of these disconnections are indicated in Fig. 22-6; the involved fiber systems include the corpus callosum, anterior commissure, uncinate temporofrontal fasciculus, occipito- and temporoparietal tracts. Extensive white matter lesions may virtually isolate certain cortical zones and result in a functional state that is the equivalent of destruction of the overlying cortical region. An example is the isolation of the perisylvian language areas from the rest of the cortex, as occurs with anoxic-ischemic infarction of border zones between major cerebral arteries (see page 409).

SYNDROMES CAUSED BY LESIONS OF THE FRONTAL LOBES

Anatomic and Physiologic Considerations

The frontal lobes lie anterior to the central or rolandic sulcus and superior to the sylvian fissure (Fig. 22-7). They are larger in humans (30 percent of the cerebrum) than in any other primate (9 percent in the macaque). Several different systems of neurons are located here, and they subserve different functions. Brodmann’s areas 4, 6, 8, and 44 relate specifically to motor activities. The primary motor cortex, i.e., area 4, is directly connected with somatosensory neurons of the anterior part of the postcentral gyrus as well as with other parietal areas, thalamic and red nuclei, and the reticular formation of the brainstem. The supplementary motor cortex, a portion of area 6, shares most of these connections. As pointed out in earlier chapters, all motor activity requires sensory guidance, and this comes from the somesthetic, visual, and auditory cortices and from the cerebellum via the ventral tier of thalamic nuclei.

Area 8 is concerned with turning the eyes and head contralaterally. Area 44 of the dominant hemisphere (Broca’s area) and the contiguous part of area 4 are "centers" of motor speech and related functions of the lips, tongue, larynx, and pharynx; bilateral lesions in these areas cause paralysis of articulation, phonation, and deglutition. The medial-orbital gyri and anterior parts of the cingulate gyri, which are the frontal components of the limbic system, take part in the control of respiration, blood pressure, peristalsis, and other autonomic functions. The most anterior parts of the frontal lobes (areas 9 to 12 and 45 to 47), sometimes referred to as the prefrontal areas, are particularly well developed in human beings but have imprecisely determined functions. They are not, strictly speaking, parts of the motor cortex in the sense that electrical stimulation evokes no direct movement; the prefrontal cortex is said to be inexcitable. Yet these areas are involved in the initiation of planned action and executive control of all mental operations, including emotional expression.

The frontal agranular cortex (areas 4 and 6) and, more specifically, pyramidal cells of layer V of the pre- and postcentral convolutions provide most of the cerebral efferent motor system that forms the pyramidal or corticospinal tract (see Figs. 3-2 and 3-3). Another massive projection from these regions is the frontopontocerebellar tract. In addition, there are other fiber systems that pass from frontal cortex to the caudate and putamen, subthalamic and red nuclei, brainstem reticular formation, substantia nigra, and in-
ferior olives as well as to the ventrolateral, mediodorsal, and
dorsolateral nuclei of the thalamus. Areas 8 and 6 are con-
ected with the ocular and other brainstem motor nuclei and
with identical areas of the other cerebral hemisphere through
the corpus callosum. A massive bundle connects the frontal
with the occipital lobe, and the uncinate bundle connects the
orbital part of the frontal lobe with the temporal lobe.

The granular frontal cortex has a rich system of connec-
tions both with lower levels of the brain (medial and ventral
nuclei and pulvinar of the thalamus) and with virtually all other
parts of the cerebral cortex, including its limbic and paralimbic
parts. As to its limbic connections, the frontal lobe is unique
among cerebrocortical areas. Electrical stimulation of the or-
bitofrontal cortex and cingulate gyrus has manifest effects on
respiratory, circulatory, and other vegetative functions, as al-
ready mentioned. These parts of the frontal cortex also receive
major afferent projections from other parts of the limbic sys-
tem, presumably to mediate the emotional responses to sensory
experiences; they, in turn, project to other parts of the limbic
and paralimbic cortices (hippocampus, parahippocampus, an-
terior pole of the temporal lobe), amygdala, and midbrain ret-
ticular formation. These frontal-limbic connections are de-
scribed in greater detail in Chap. 25.

Blood is supplied to the medial parts of the frontal lobes
by the anterior cerebral artery and to the convexity and deep
regions by the superior (rolandic) division of the middle ce-
rebral artery.

With respect to the physiology of the frontal lobes, the
literature is replete with unsubstantiated claims. Here are pre-
sumed to reside the mechanisms that govern personality, char-
acter, motivation, and our unique capacities for abstract think-
ing, introspection, and planning. These qualities and traits do
not lend themselves to easy definition and study or to discrete
localization. Most of them are too subtle to isolate and mea-
ure. Except for the more posterior frontal mechanisms sub-
serving motor speech and motility and certain behaviors relat-
ing to impulse (conation), neurologists have recognized that
the other features of frontal lobe disease are more abstruse.

Clinical Effects of Frontal Lobe Lesions

For descriptive purposes, the clinical effects of frontal lobe lesions
can be grouped under the following categories: (1) motor abnor-
malities related to the prerolandic motor cortex; (2) speech and
language disorders related to the dominant hemisphere; (3) incon-
tinence of bladder and bowel; (4) impairment of certain cognitive
functions, especially attention, concentration, capacity for sus-
tained mental activity, and ability to shift from one line of thought
or action to another—i.e., both impersistence and perseveration;
(5) akinesia and lack of initiative and spontaneity (apathy and abu-
lia); (6) other changes in personality, particularly in mood and self-
control (disinhibition of behavior); and (7) a distinctive abnormal-
ity of gait (page 106).

With regard to the last three of these having to do with be-
havior, the anterior half of the brain is in a general sense committed
to the monitoring and execution of all cerebral activity. This means
that all activities—motor, cognitive, and emotional—are planned
and initiated here. Of necessity in such a scheme, there must also be
inhibitory mechanisms that control or modulate behavior. Thus,
aside from the overt abnormalities of motor, speech, and voluntary
movement, lesions of the frontal lobes give rise to a loss of drive,
impairment of consecutive planning, as well as inability to maintain
serial relationships of events and to shift easily from one mental
activity to another—at times in combination with the release (dis-
inhibition) of sucking, grasping, and groping reflexes and other so-
called utilization behaviors. Furthermore, in the emotional sphere,
frontal lobe lesions may cause anhedonia (lack of pleasure), apathy,
loss of self-control, disinhibited social behavior, and euphoria, as
described further on.

Motor Abnormalities Voluntary movement involves the motor
cortex in its entirety or at least large parts of it, and of the various
effects of frontal lobe lesions, most is known about the motor ab-
normalities. Electrical stimulation of the motor cortex elicits con-
traction of corresponding muscle groups on the opposite side of
the body; focal seizure activity has a similar effect. Stimulation of
Brodmann’s area 4 produces movement of discrete muscle groups
or, if sufficiently refined, of individual muscles. Repertoires of
larger coordinated movements are evoked by stimulation of area 6,
the premotor cortex.

Lesions in the posterior part of the frontal lobe cause spastic
paralysis of the contralateral face, arm, and leg. Involved are the

Figure 22-6. Connections involved in naming a seen object and in reading. The
visual pattern is transferred from the visual cortex and association areas to the
angular gyrus, which arouses the auditory pattern in the Wernicke area. The au-
ditory pattern is transmitted to the Broca’s area, where the articulatory form is
aroused and transferred to the contiguous face area of the motor cortex. With
destruction of the left visual cortex and splenium (or intervening white matter),
words perceived in the right visual cortex cannot cross over to the language areas
and the patient cannot read.
Ablation of the right or left supplementary motor areas was found by Laplane and colleagues to cause mutism, contralateral motor neglect, and impairment of bibrachial coordination. On the basis of blood flow studies, Roland and colleagues and Fuster have suggested that an important function of the supplementary motor area is the ordering of motor tasks or the recall of memorized motor sequences—further evidence of the executive functions of the frontal lobes. Some insight into motor organization in supplementary motor cortex is given by seizures originating there; they give rise to curious postures such as a fencing position or flailing of the opposite arm. Temporary paralysis of contralateral eye turning and sometimes head turning follows a destructive lesion in area 8, on the dorsolateral aspect (convexity) of the cerebral cortex, often referred to as the frontal eye field (see Fig. 22-1). Seizure activity in this area causes a tonic deviation of the head and eyes to the opposite side. Destruction of Broca’s convolution (areas 44 and 45) and the adjacent insular and motor cortex of the dominant hemisphere result in a reduction or loss of motor speech, and of agraphia, and apraxia of the face, lips, and tongue as described in Chap. 23.

When the lesions of the motor parts of the frontal lobe are bilateral, there is a quadriplegia or quadriparesis in which the weakness is not only more severe but also more extensive than in unilateral lesions, affecting cranial muscles (pseudobulbar palsy) as well as spinal ones.

Damage to the cortices anterior to areas 6 and 8—i.e., to areas 9, 10, 45, and 46—the prefrontal cortex, and also the anterior cingulate gyri, has less easily defined effects on motor behavior. The prefrontal cortex is heteromodal and has strong reciprocal connections with the visual, auditory, and somatosensory cortices. Of these, the visuomotor relationships are the most powerful. These frontal areas as well as the supplementary motor areas are involved in the planning and initiation of sequences of movement, as indicated in Chap. 4. In the monkey, for example, when a visual signal evokes movement, some of the prefrontal neurons become active immediately preceding the motor response; other prefrontal neurons are activated if the response is to be delayed. With prefrontal lesions on one side or the other, a series of motor abnormalities occur, ranging through slight grasping and groping responses (“instinctive grasping” of Denny-Brown), a tendency to imitate the examiner’s gestures and to compulsively manipulate objects that are in front of the patient (imitation and utilization behavior described by Lhermitte), reduced and delayed motor and mental activity (abulia), motor perseveration or impersistence (with left and right hemispheric lesions, respectively), and paratonic rigidity on passive manipulation of the limbs (oppositional resistance, or gegenhalten).

An ataxia of the contralateral limbs has been attributed to prefrontal lesions, but careful anatomic verification is lacking. (In our experience, a unilateral ataxia from a cerebral lesion has been related rarely to a lesion of the opposite parietal lobe). The condition described by Bruns due to a frontal lobe lesion was designated by him as an ataxia of gait; he made no reference to an ataxia of limb movements. This disorder is often also referred to as an apraxia of
gait—inappropriately in our opinion, because the term apraxia is best used to describe psychic inability to carry out a commanded or learned motor task, not an ingrained one (page 48). What is meant by these terms has never been clearly specified, but broadly speaking, they signify a loss of the ability to use the lower limbs in the act of walking that cannot be explained by weakness, loss of sensation, or ataxia. The patient retains these fundamental motor and sensory functions when examined in bed and can even make motions that simulate walking while seated or reclining. As detailed in Chap. 7, the resultant pattern is a slowed, slightly imbalanced, and short-stepped gait with the torso and legs not properly in phase when placed in motion, to which may be added the feature of “magnetic” gait, where one or both feet appear to be stuck to the ground as the body moves forward. Probably the basal ganglia and their connections to the frontal lobes are involved in these cases. As mentioned, the steps are shortened to a shuffle and balance is precarious; with further deterioration, the patient can no longer walk or even stand (a condition called astasia-abasia). Cerebral paraplegia in flexion is the end stage; the affected individual lies curled up in bed, unable even to turn over (see Chap. 7 for further discussion).

Less is known about the extreme degrees of hyperactivity (“organic drivenness”) induced in the macaque by bilateral lateral-orbital lesions and occasionally observed in humans after encephalitis or trauma, as noted below. Possibly, compulsive behavior (including tic) is related in some manner to this state and more particularly to caudatal-frontal lesions. In many instances, patients with frontal lobe lesions are inclined to manipulate objects placed before them (utilization behavior) or to imitate the gestures of others.

Incontinence is another manifestation of frontal lobe disease. Right- or left-sided lesions involving the posterior part of the superior frontal gyrus, the anterior cingulate gyrus, and the intervening white matter result in a loss of control of micturition and defecation (Andrew and Nathan). There is no warning of fullness of the bladder or of the imminence of urination or bowel evacuation, and the patient is surprised at suddenly being wet or soiled. Less complete forms of the syndrome are associated with frequency and urgency of urination during waking hours. The patient is embarrassed unless an element of indifference is added when the more anterior (nonmotor) parts of the frontal lobes are the sites of disease.

In the spheres of speech and language, a number of abnormalities other than Broca’s aphasia appear in conjunction with disease of the frontal lobes—laconic speech, lack of spontaneity of speech, telegraphic speech (agrammatism), loss of fluency, perseveration of speech, a tendency to whisper instead of speaking aloud, and dysarthria. These are more prominent with left-sided lesions and are fully described in Chap. 23.

In sum, one can say that all parts of the frontal lobes are involved in all spheres of motor activity, from the planning stages to ultimate execution. This applies not only to willed movement but to all postural reactions and habitual activity as well.

Cognitive and Intellectual Changes In general, when one speaks of cognitive and behavioral aspects of frontal lobe function, reference is made to the more anterior (prefrONTAL) parts rather than the motor and linguistic parts. Here one faces a paradox. These most recently developed parts of the human brain, sometimes called the “organ of civilization,” have the most elusive functions.

The effects of lesions of the frontal lobes were first divulged by Harlow’s famous case, published in 1868; it has been the subject of numerous monographs ever since. His patient, Phineas Gage, was a capable, God-fearing foreman of a railroad gang who became irreverent, dissipated, irresponsible, and vacillating (he also con- fabulated freely) following an injury in which an explosion drove a large iron tamping bar into his frontal lobes. In Harlow’s words, “he was no longer Gage.” Another similarly dramatic example was Dandy’s patient (the subject of a monograph by Brickner), who underwent a bilateral frontal lobotomy during the removal of a meningioma. Feuchtwanger, in a clinical study of 200 cases of frontal lobe injury, was impressed with the lack of initiative, changes in mood (euphoria), and inattentiveness, without intellectual and memory deficits; Rylander, in a classic monograph, described similar changes in patients with unilateral and bilateral frontal lobectomies (see below). Kleist, under the heading of alogia, stressed the importance of loss of capacity for abstract thought, as shown in tests of analogies, proverbs, definitions, etc. In chimpanzees, Jacobsen observed that the removal of the premotor parts of the frontal lobes led to social indifference, tameness, placidity, forgetfulness, and difficulty in problem-solving—findings that led Egas Moniz, in 1936, to perform prefrontal lobotomies on psychotic patients (see Damasio). This operation and its successor, prefrontal leukotomy (undercutting of the prefrontal white matter), reached their height of popularity in the 1940s and (tragically) provided the opportunity to study the effects of a wide range of frontal lobe lesions in a large number of patients.

The findings in patients who underwent frontal leukotomy have been the subject of endless controversy. Some workers claimed that there were few or no discernible effects of the operation, even with bilateral lesions. Others insisted that if the proper tests were used, a series of predictable and diagnostic changes in cognition and behavior could be demonstrated. The arguments pro and con and the inadequacies of many of the studies, both in methods of testing and in anatomic verification of the lesions (the extent and location of the lesions varied considerably, and this influenced the clinical effects), have been well summarized by Walsh. Admittedly, in patients who underwent bilateral frontal lobotomy, there was little if any impairment of memory function or of cognitive function as measured by intelligence tests and certainly no loss of alertness and orientation. And some patients who had been disabled by schizophrenia, anxious depression, obsessive-compulsive neurosis, or a chronic pain syndrome did improve with respect to their psychiatric and pain symptoms. However, many patients were left with changes in personality, much to the distress of their families. They were indifferent to the feelings of others; gave no thought to the effects of their conduct; were tacitless, distractible, and socially inept; and were given to euphoria and emotional outbursts.

Luria had an interesting conception of the role of the frontal lobes in intellectual activity. He postulated that problem solving of whatever type (perceptual, constructive, arithmetical, psycholinguistic, or logical—definable also as goal-related behavior) proceeds in four steps: (1) the specification of a problem (in other words, a goal is perceived and the conditions associated with it are set); (2) formulation of a plan of action or strategy, requiring that certain linguistic activities be initiated in orderly sequence; (3) execution, including implementation and control of the plan; and (4) checking or comparing the results against the original plan to see if it was adequate. Obviously such complex psychologic activity must implicate many parts of the cerebrum and will suffer to some extent from a lesion in any of the parts that contribute to the func-
tional system. Luria found that when the frontal lobes are injured by disease, there was not only a general psychomotor slowing and easy distractibility but also an erroneous analysis of the above-listed conditions of the problem. “The plan of action that is selected quickly loses its regulating influence on behavior as a whole and is replaced by a perseveration of one particular link of the motor act or by the influence of some connection established during the patient’s past experience.” Furthermore, there was a failure to distinguish the essential sequences in the analysis and to compare the final solution with the original conception of the problem. Plausible as this scheme appears, like Goldstein’s “loss of the abstract attitude” (the patient thinks concretely, i.e., he reacts directly to the stimulus situation), such psychophysiological analyses of the mental processes are highly theoretical, and the factors to which they refer are not easily measured.

In modern parlance, the frontal lobe, and particularly its prefrontal components, is said to exert an “executive function,” referring here to the overall control of other cognitive functions. This allows for a type of self-monitoring that guides the selection of strategies to solve problems, the inhibition of incorrect responses, the ability to deal with change in focus and novelty in tasks, and probably to be able to generalize from experience. Indeed, all ability to adapt to changes in circumstance requires this executive function. Unlike some of the psychic properties mentioned above, these are subject to measurement by testing, but they are observable during the clinical examination as a deterioration in problem solving, by repetitiveness and stereotypies, and by ineptitude in managing simple social situations. Probably the trouble all individuals experience in maintaining a stream of thought when interrupted tests this function.

**Other Alterations of Behavior and Personality** A lack of initiative and spontaneity is the most common effect of frontal lobe disease, and it is much easier to observe than to quantitate. With relatively mild forms of this disorder, patients exhibit an idleness of thought, speech, and action, and they lapse into this state without complaint. They are tolerant of most conditions in which they are placed, though they may act unreasonably for brief periods if irritated, seemingly unable to think through the consequences of their remonstrances. They let members of the family answer questions and “do the talking,” interjecting a remark only rarely and unpredictably. Questions directed to such patients may evoke only brief, unqualified answers. Once started on a task, they may persist in it (“stimulus bound”); i.e., they tend to perseverate. Fuster, in his studies of the prefrontal cortex, emphasizes the failure over time to maintain events in serial order (impairment of temporal grading) and to integrate new events and information with previously learned data. Placidity is a notable feature of the behavior. Worry, anxiety, self-concern, hypochondriasis, complaints of chronic pain, and depression are all reduced by frontal lobe disease, as they are by frontal lobotomy.

Extensive and bilateral frontal lobe disease is accompanied by a quantitative reduction in all psychomotor activity. The number of movements, spoken words, and thoughts per unit of time diminish. Milder degrees of this state, associated with only a delay in responses, are called *abulia* (page 359); the most severe degrees take the form of *akinetic mutism* (page 305) wherein a nonparalyzed patient, alert and capable of movement and speech, lies or sits motionless and silent for days or weeks on end. The localization of this condition is quite imprecise. It has been attributed to bilateral lesions in the ventromedial frontal regions or frontal-diencephalic connections. Laplane found that the lack of motivation of the patient with bifrontal lesions and bipallidal lesions to be the same, though one would expect the latter to be manifest more as a bradykinesia than as a bradypnea (slowness of thinking). Benson (and Kleist and others before him) related the syndrome of apathy and lack of initiative to lesions in the sagittal or frontal medial frontal cortex, and a facetious, unguarded, and socially inappropriate state (see below) to orbital and dorsolateral frontal lesions. This division has held up only broadly in our experience.

The opposite state, in a sense, is the hyperactivity syndrome, or “organic drivenness,” described by von Economo in children who had survived an attack of encephalitis lethargica. In our patients, this syndrome has been produced by combined frontal and temporal lobe lesions, usually traumatic but also encephalitic, although exact clinicopathologic correlations could not be made. Such patients may also exhibit brief but intense involvement with some meaningless activity, such as sorting papers in an attic or hoarding objects or food. Combativeness and extreme insomnia or an otherwise disrupted sleep cycle are often part of the syndrome. The hyperactivity of young boys and the mania or hypomania of manic-depressive disease, despite similar symptoms, also lack a known anatomic basis.

In addition to the disorders of initiative and spontaneity, frontal lobe lesions result in a number of other changes in personality and behavior. These, too, are easier to observe in the patient’s natural environment—for example, by his family—than to measure by psychologic tests. It has been difficult to find a term for all these personality changes. Some patients, particularly those with infratemporal lesions, feel compelled to make silly jokes that are inappropriate to the situation—so-called *Witzelsucht* or moria; they are socially uninhibited and lack awareness of their behavior. The patient is no longer the sensitive, compassionate, effective human being that he once was, having lost his usual ways of reacting with affection and consideration to family and friends. In more advanced instances, there is an almost complete disregard for social conventions and an interest only in immediate personal gratification. The patient seems to lose an inherent “theory of mind,” through which the normal individual recognizes the motivations and thought processes of other sapient persons; this results in the inability to incorporate these factors into the patient’s responses. These changes, observed characteristically in lobotomized patients, came to be recognized as too great a price to pay for the loss of neurotic traits, pain, depression, and “tortured self-concern,” for which reasons lobotomies were done; hence the procedure raised public outcry and became obsolete.

The effect of unilateral prefrontal lesions is a question that continues to vex clinicians. If the lesions are small, their effects are undetectable; even a large lesion, such as a tumor, may long escape detection. Rylander, by careful psychologic testing, has shown that patients with lesions of either frontal lobe manifest a slight elevation and instability of mood, with increased talkativeness and a tendency to joke, lack of tact, inability to adapt to a new situation, and loss of initiative—changes that in our experience are more readily recognized if the lesion is on the right. Large left frontal lesions have been more prone to cause abulia in our material.

In general, we agree that the greatest cognitive-intellectual deficits relate to lesions in the dorsolateral parts of the prefrontal lobes and that the greatest personality, mood, and behavioral changes stem from lesions of the medial-orbital parts, although the two types of disorder often merge with one another. The diagnosis of lesions in the orbital regions is facilitated by the finding of uni-
lateral anosmia or optic atrophy, as occurs with a meningioma of the olfactory groove.

Our experience with frontal lobe lesions—derived mainly from patients with trauma, infiltrating glioma, or ruptured aneurysms—affirms most of the statements above. Most apparent is the abulic-hypokinetic disorder that seems to slow the mental processes involved in all forms of cerebral performance. Inattentiveness and impersistence in all assigned tasks are the other major features of this disorder; at the same time, seemingly paradoxically, there may be an impulsiveness in all responses and perseveration. Such a state of slowness and inattentiveness cannot be specifically ascribed to prefrontal lesions, since it may be a reflection of a more general impairment of the thalamolimbic or reticular activating thalamocortical system. Indeed, bilateral medial thalamic lesions may give rise to the same syndrome, and Degos and colleagues have described a severe “frontal lobe syndrome” in association with bilateral lesions of the anterior cingulate gyrus. It is noteworthy that these structures have close connections with the prefrontal cortices.

Although the frontal lobes are the subject of a vast literature and endless speculation (see reviews of Stuss and Benson and of Damasio), a unified concept of their function has not emerged—probably because they are so large and include several heterogeneous systems. There is no doubt that the mind is changed by disease of the prefrontal parts of the frontal lobes, but often it is difficult to say exactly how it is changed. Perhaps at present it is best to regard the frontal lobes as the part of the brain that quickly and effectively orient and drives the individual, with all the perceptions and concepts formed from past life experiences, toward action that is projected into the future.

Psychologic tests of particular value in establishing the presence of frontal lobe disease are generally constructed to detect the ability to persist in a task and to switch mental focus on demand. They include the Wisconsin card-sorting test, the Stroop color-naming test, sequencing of pictures, “trail making” (a two-part test in which the patient draws lines, first connecting randomly arrayed numbers on a paper in order and then connecting numbers and letters that correspond in order) the verbal equivalent of trail making (see below), and the three-step hand posture test of Luria. The last two tests are a popular part of the bedside neurologic evaluation of patients with suspected frontal lobe lesions. The alphabet-number test requires the patient to give each letter of the alphabet followed by the corresponding number (A-1, B-2, C-3, etc.). In the Luria test, the patient is asked to imitate, then reproduce on his own, a sequence of three hand gestures, typically slapping the opposite outstretched palm, hitting the palm with a closed fist, and then by striking it with the side of the open hand. Patients with frontal lesions on either or both sides have difficulty performing the test in correct sequence, often perseverating, balking, or making unwanted gestures. Luria pointed out that the natural kinetic smoothness of transition from one hand position to the next is disrupted and there is a tendency to perseverate. (He favored testing with the sequence of arm thrusting forward, clenching the fist, and forming a ring with the first two fingers.) However, it should be kept in mind that similar impairments of performance may occur with all manner of confusional and inattentive states and with apraxias. More complex mental acts that may be easily tested and betray frontal lobe disease but are less specific, in that they are also disordered by lesions in other brain regions, include serial subtraction (“working memory”), interpretation of proverbs, tests of rapid motor response, and others.

Effects of frontal lobe disease may be summarized as follows:

I. Effects of unilateral frontal disease, either left or right
   A. Contralateral spastic hemiplegia
   B. Slight elevation of mood, increased talkativeness, tendency to joke inappropriately (Witzelsucht), lack of tact, difficulty in adaptation, loss of initiative
   C. If entirely prefrontal, no hemiplegia; grasp and suck reflexes or instinctive grasping may be released
   D. Anosmia with involvement of orbital parts

II. Effects of right frontal disease
   A. Left hemiplegia
   B. Changes as in I, B, C, and D

III. Effects of left frontal disease
   A. Right hemiplegia
   B. Motor speech disorder with agraphia, with or without apraxia of the lips and tongue (see Chap. 23)
   C. Sympathetic apraxia of left hand (see page 49)
   D. Loss of verbal associative fluency; perseveration
   E. Changes as in I, B, C, and D

IV. Effects of bifrontal disease
   A. Bilateral hemiplegia
   B. Spastic bulbar (pseudobulbar) palsy
   C. If prefrontal, abulia or akinetic mutism, lack of ability to sustain attention and solve complex problems, rigidity of thinking, bland affect, social ineptitude, behavioral disinhibition, inability to anticipate, labile mood, and varying combinations of grasping, sucking, obligate imitative movements, utilization behavior.
   D. Decomposition of gait and sphincter incontinence

SYNDROMES CAUSED BY LESIONS OF THE TEMPORAL LOBES

Anatomic and Physiologic Considerations

The boundaries of the temporal lobes are indicated in Fig. 22-7. The sylvian fissure separates the superior surface of each temporal lobe from the frontal lobe and anterior parts of the parietal lobe. There is no definite anatomic boundary between the temporal lobe and the occipital or inferior-posterior part of the parietal lobe, but the angular gyrus serves as a landmark for the latter.

The inferior branch of the middle cerebral artery supplies the convexity of the temporal lobe, and the temporal branch of the posterior cerebral artery supplies the medial and inferior aspects, including the hippocampus.

The temporal lobe includes the superior, middle, and inferior temporal, lateral occipitotemporal, fusiform, lingual, parahippocampal, and hippocampal convolutions and the transverse gyri of Heschl; the last of these constitute the primary auditory receptive area and are located within the sylvian fissure. This area has a tonotopic arrangement: fibers carrying high tones terminate in the medial portion of the gyrus and those carrying low tones, in the lateral and more rostral portions (Merzenich and Brugge). The planum temporale (area 22), an integral part of the auditory cortex, lies immediately posterior to Heschl’s convolutions, on the superior surface of the temporal lobe. The left planum is larger in right-handed individuals. There are rich reciprocal connections between...
the medial geniculate bodies and Heschl’s gyri. The latter project to the unimodal association cortex of the superior temporal gyrus, which, in turn, projects to the paralimbic and limbic regions of the temporal lobe and to temporal and frontal heteromodal association cortices and the inferior parietal lobe. There is also a system of fibers that projects back to the medial geniculate body and to lower auditory centers. The cortical receptive zone for labyrinthine impulses is less well demarcated than the one for hearing but is probably situated on the inferior bank of the sylvian fissure, just posterior to the auditory area. Least well delimited is the role of the medial parts of the temporal lobe in olfaction and gustatory perception, although seizure foci in the region of the uncus (uncinate seizure) often excite hallucinations of these senses.

The middle and inferior temporal gyri (areas 21 and 37) receive a massive contingent of fibers from the striate cortex (area 17) and the parastriate visual association areas (areas 18 and 19). These temporal visual areas make abundant connections with the medial limbic, rhinencephalic (olfactory), orbitofrontal, parietal, and occipital cortices, allowing for an intimate interconnectedness between the cortices subserving vision and hearing.

The superior part of the dominant temporal lobe is concerned with the acoustic or receptive aspects of language as discussed in Chap. 23, which is devoted to this subject. The middle and inferior convolutions are sites of visual discriminations; they receive fiber systems from the striate and parastriate visual cortices and, in turn, project to the contralateral visual association cortex, the parietal heteromodal cortex, the superior temporal cortex, and the limbic and paralimbic cortex. Presumably these systems subserve such functions as spatial orientation, estimation of depth and distance, stereoscopic vision, and hue perception. Similarly, the unimodal auditory cortex is closely connected with a series of auditory association areas in the superior temporal convolution, and the latter are connected with prefrontal and temporoparietal heteromodal areas and the limbic areas (see Mesulam). Most of these auditory connections have been worked out in the macaque, but the limited number of well-studied lesions in patients suggest that they are also involved in complex verbal and nonverbal auditory discriminations in humans.

The hippocampus was formerly thought to be related to the olfactory system, but it is now known that lesions here do not alter the sense of smell. The most important functions of the hippocampus and other structures of the hippocampal formation (dentate gyrus, subiculum, entorhinal cortex, and parahippocampal gyrus) are in learning and memory, already discussed in Chap. 21. There is an abundance of connections between the mediotemporal lobe and the entire limbic system. For this reason MacLean referred to these parts as the “visceral brain,” and Williams, as the “emotional brain.” Also included in this anatomic concept are the hippocampus, the amygdaloid nuclei, the fornices and limbic portions of the inferior and medial frontal regions, the cingulate cortices, and the septal and associated subcortical nuclei (see Chap. 25).

Most of the temporal lobe cortex, including Heschl’s gyri, has nearly equally developed pyramidal and granular layers. In this respect, it resembles more the granular cortex of the frontal and prefrontal regions and inferior parts of the parietal lobes. Unlike the six-layered neocortex, the hippocampus and dentate gyrus are typical of the phylogenetically older three-layered allocortex.

A massive fiber system projects from the striate and parastriate zones of the occipital lobes to the inferior and medial parts of the temporal lobes. The temporal lobes are connected to one another through the anterior commissure and middle part of the corpus callosum; the inferior or uncinate fasciculus connects the anterior temporal and orbital frontal regions. The arcuate fasciculus connects the posterolateral temporal lobe to the motor cortex and Broca’s area (see page 421).

Physiologically, two functional correlations stand out—that the temporal lobe is the great integrator of “sensations, emotions, and behavior” (Williams) and that it is continuously active throughout life. The temporal lobe seems to be the site where sensory modalities are integrated into ultimate self-awareness (the cartesian view of consciousness of one’s self as a person with a mind). Similar suprasensory integrative mechanisms are operative in the parietal lobe, but only in the temporal lobe are they brought into close relationship to one’s instinctive and emotional life. Self-awareness also requires a coherent and sequential stream of thought. Where precisely the inner “stream of consciousness” (James’s term for constant thinking) is perceived is still an open question. Given the requirement that it be close to other integrated sensory experiences and that it incorporate the temporal lobe functions of both language and memory, a focus in the temporal lobes seems likely. During the middle years of the twentieth century, the temporal lobe was the principal focus of studies of cerebral function. Some hint of its role in our personal and emotional life was suggested by Hughlings Jackson in the nineteenth century, derived from his insightful analysis of the psychic states accompanying temporal lobe seizures. Later, the observations of Penfield and his collaborators on the effects of stimulating the temporal lobes in the conscious epileptic patient revealed something of its complex functions. There followed a large volume of writings on its anatomy, the neuronal networks and circuits by which it was connected to other cortical and subcortical structures, and the effects of ablation on emotion, behavior, and sensory perception. The classic writings on this subject include Williams’s chapter on temporal lobe syndromes in the Handbook of Clinical Neurology and the monographs by Penfield and Rasmussen (The Cerebral Cortex of Man) and by Alajouanine and colleagues (Les Grandes Activités du Lobe Temporale).

Clinical Effects of Temporal Lobe Lesions

The symptoms that arise as a consequence of disease of the temporal lobes may, for convenience of exposition, be divided into disorders of the special senses (visual, auditory, olfactory, and gustatory), time perception, language, memory, emotion, and behavior. Of central importance also are the roles of the superior part of the dominant lobe and its hippocampal and limbic parts in language, handedness, memory and learning functions, and the emotional life of the individual. Several of these functions and their derangements are of such scope and importance that they are accorded separate chapters. Language is discussed in Chap. 23, memory in Chap. 21, and the neurology of emotion and behavior in Chap. 25; these subjects are omitted from further discussion here.

Visual Disorders Already in Chap. 13 (on vision) it was pointed out that lesions of the white matter of the central and posterior parts of the temporal lobe characteristically involve the lower arching fibers of the geniculocalcarine pathway (Meyer’s loop). This results in a lower homonymous quadrantanopia, usually not perfectly congruent. However, there is considerable variability in the arrangement of visual fibers as they pass around the temporal horn of the lateral ventricle, accounting for the smallness of the field defect in some patients after temporal lobectomy or stroke and
extension into the inferior field in others. Quadrantanopia from a
dominant (left-sided) lesion is often combined with aphasia.

Bilateral lesions of the temporal lobes render a monkey psy-
chically blind. It can see and pick up objects but does not recognize
them until they are explored orally. Natural emotional reactions
such as fear are lost. This syndrome, named for Kluver and Bucy,
has been identified only in partial form in humans (page 448).

Visual hallucinations of complex form, including ones of the
patient himself (autoscopy), appear during temporal lobe seizures.
In stimulation studies, Penfield was able to induce what he called
“interpretive illusions” (altered impressions of the present) and to
reactivate past experiences quite completely and vividly in asso-
ciation with their original emotions. Temporal lobe abnormalities
may also distort visual perception; seen objects may appear too
large (macropsia) or small (micropsia), too close or far away, or
unreal. Some visual hallucinations have an auditory component: an
imaginary figure may speak and move and, at the same time, arouse
intense emotion in the patient. The entire experience may seem
unnatural and unreal but is unlike the visuospatial disorders of the
body schema that are considered further on with disorders of the
parietal lobe.

Cortical Deafness Bilateral lesions of the transverse gyri of
Heschl, while rare, are known to cause a central deafness.
Henschen, in his famous review of 1337 cases of aphasia that had
been reported up to 1922, found 9 in which these parts were de-
stroyed by restricted vascular lesions, with resulting deafness.
There are now many more cases of this type in the medical lit-
erature; lesions in other parts of the temporal lobes have no effect on
hearing. These observations are the basis for the localization of the
primary auditory receptive area in the cortex of the transverse gyri
(chiefly the first) on the posterosuperior surface of the temporal
lobe, deep within the sylvian fissure (areas 41 and 42). Subcortical
lesions, which interrupt the fibers from both medial geniculate bod-
dies to the transverse gyri, as in the two cases described by Tanaka
and colleagues, have the same effect. With left-sided superotem-
poral lesions, there is usually an aphasia because of the proximity
of the transverse gyri to the superotemporal association cortex. Hé-
caen has remarked that cortically deaf persons may seem to be
unaware of their deafness, a state similar to that of blind persons
who act as though they could see (the latter is called Anton syn-
drome, as described further on).

Unilateral lesions of Heschl’s gyri were for a long time be-
thieved to have no effect on hearing; it has been found, however,
that a number of subtle deficits can be detected with careful testing.
If very brief auditory stimuli are delivered, the threshold of sen-
sation is elevated in the ear opposite the lesion. Also, while uni-
ilateral lesions do not diminish the perception of pure tones or
clearly spoken words, the ear contralateral to a temporal lesion is
less efficient if the conditions of hearing are rendered more difficult
(binaural testing). For example, if words are slightly distorted (elec-
tronically filtered to alter consonants), they are heard less well in
the ear contralateral to the lesion. In addition, the patient has more
difficulty in equalizing the volume of sounds that are presented to
both ears and in perceiving rapidly spoken numbers or different
words presented to the two ears (dichotic listening).

Auditory Agnosias Lesions of the secondary (unimodal associ-
ation) zones of the auditory cortex—area 22 and part of area 21—

have no effect on the perception of sounds and pure tones. How-
ever, the perception of complex combinations of sounds is severely
impaired. This impairment, or auditory agnosia, takes several forms—inability to recognize sounds, different musical notes
(amusia), or words—and presumably each has a slightly different
anatomic basis.

In agnosia for sounds, auditory sensations cannot be distin-
guished from one another. Such varied sounds as the tinkling of a
bell, the rustling of paper, running water, and a siren all sound alike.
The condition is usually associated with word deafness (page 421
and below) or with amusia. Hécaen observed an agnosia for sounds
alone in only two cases; one patient could identify only half of 26
familiar sounds, and the other could recognize no sound other than
the ticking of a watch. Yet in both patients the audiogram was
normal, and neither had trouble understanding spoken words. In
both, the lesion involved the right temporal lobe and the corpus
callosum was intact.

Amusia proves to be more complicated, for the appreciation
of music has several aspects: the recognition of a familiar melody
and the ability to name it (musicality itself); the perception of pitch,
timbre, and rhythm; and the ability to produce, read, and write
music. There are many reports of musicians who became word-
deaf with lesions of the dominant temporal lobe but retained their
recognition of music and their skill in producing it. Others became
agnosic for music but not for words, and still others were agnosic
for both words and music. According to Segarra and Quadfasel,
impaired recognition of music results from lesions in the middle
temporal gyrus and not from lesions at the pole of the temporal
lobe, as had been postulated by Henschen. Many other studies im-
licate the superior temporal gyrus in these deficits. A loss of the
ability to perceive and produce rhythm may or may not be asso-
ciated. In any case, the temporal lobe opposite that responsible for
language (i.e., the right) is implicated in almost all cases.

That the appreciation of music is impaired by lesions of the
nondominant temporal lobe finds support in Milner’s studies of
patients who had undergone temporal lobectomy. She found a sta-
tistically significant lowering of the patient’s appreciation of the
duration of notes, timbre, intensity of sounds, and memory of mel-
odies following right temporal lobectomy; these abilities were
preserved in patients with left temporal lobectomies, regardless of
whether Heschl’s gyri were included. Shankweiler had made sim-
ilar observations, but in addition found that patients had difficulty
in denoting a note or naming a melody following left temporal
lobectomies.

More recent observations permit somewhat different inter-
pretations. Tramo and Bharucha examined the mechanisms mediating
the recognition and discrimination of timbre (the distinctive tonal
quality produced by a particular musical instrument) in patients
whose right and left hemispheres had been separated by callosot-
omy. They found that timbre could be recognized by each hemi-
sphere—somewhat better by the left hemisphere than by the right.
Also, it was observed that lesions of the right auditory cortex im-
paired the recognition of melody (the temporal sequence of pitches)
and of harmony (the sounding of simultaneous pitches). However,
if words were added to the melody, then either a left- or right-sided
lesion impaired its recognition (Samson and Zatorre). From func-
tional imaging studies, it appears that the left inferior frontal region
is activated by tasks that involve the identification of familiar music
(Platel et al), as if this were a semantic test, but passively listening
to melodies activates the right superior temporal and occipital
regions (Zatorre et al).
Taken together, these data suggest that the nondominant hemisphere is important for the recognition of harmony and melody (in the absence of words), but that the naming of musical scores and all the semantic (writing and reading) aspects of music require the integrity of the dominant temporal and probably the frontal lobes as well.

**Word-Deafness (Auditory Verbal Agnosia)** In essence, word-deafness is a failure of the left temporal lobe function in decoding the acoustic signals of speech and converting them into understandable words. This is the essential element of Wernicke’s aphasia and is discussed on page 421. However, word-deafness can occur by itself, without other features of Wernicke’s aphasia. Also, as mentioned above, verbal agnosia may be combined with agnosia for itself, without other features of Wernicke’s aphasia. As also discussed on page 421. However, word-deafness can occur by ability words. This is the essential element of Wernicke’s aphasia and the acousticsignalsofspeechandconvertingthemintounderstandable words.

**Auditory Illusions** Temporal lobe lesions that leave hearing intact may cause a hearing disorder in which sounds are perceived as being louder or less loud than normal. Sounds or words may seem strange or disagreeable, or they may seem to be repeated, a kind of sensory perseveration. If auditory hallucinations are also present, they may undergo similar alterations. Such paracusias may last indefinitely and, by changing timbre or tonality, alter musical appreciation as well.

**Auditory Hallucinations** (See also Chap. 15.) With lesions of the temporal lobes, these may be elementary (murmurs, blowing, sound of running water or motors, whistles, clangs, sirens, etc.), or they may be complex (musical themes, choruses, voices). Usually sounds and musical themes are heard more clearly than voices. Patients may recognize hallucinations for what they are, or they may be convinced that the voices are real and respond to them with intense emotion. Hearing may fade before or during the hallucination.

In temporal lobe epilepsy, the auditory hallucinations are known to occur alone or in combination with visual or gustatory hallucinations, visual distortions, dizziness, and aphasia. There may be hallucinations based on remembered experiences (experiential hallucinations, in the terminology of Penfield and Rasmussen).

The anatomy of lesions underlying auditory illusions and hallucinations has been incompletely studied. In some instances these sensory phenomena have been combined with auditory verbal (or nonverbal) agnosia; the superior and posterior parts of the dominant or both temporal lobes were then involved. Clinicanatomic correlation is difficult in cases associated with tumors that distort the brain without completely destroying it and that also cause edema of the surrounding tissue. Moreover, it is often uncertain whether symptoms have been produced by destruction of tissue or by excitation, i.e., by way of seizure discharges, which act in a fashion similar to electrical stimulation of the auditory cortical areas. Elementary hallucinations and dreamy states have been reported with lesions of either temporal lobe, whereas the more complex auditory hallucinations and particularly polymodal ones (visual plus auditory) occur more often with left-sided lesions. It should also be noted that complex but uniformed auditory hallucinations (e.g., the sound of an orchestra tuning up), as well as entire strains of music and singing, occur with lesions that appear to be restricted to the pons (pontine auditory hallucinosis, as noted in Chap. 15).

It is tempting to relate complex auditory hallucinations to disorders in the auditory association areas surrounding Heschl’s gyri, but the available data do not justify such an assumption. In schizophrenic patients, the areas activated during a period of active auditory hallucinosis include not only Heschl’s gyri but also the hippocampus and other widely distributed structures in the dominant hemisphere (see Chap. 58).

**Vestibular Disturbances** In the superior and posterior part of the temporal lobe (posterior to the primary auditory cortex), there is an area that responds to vestibular stimulation by establishing one’s sense of verticality in relation to the environment. If this area is destroyed on one side, the only clinical effect may be an illusion that the environment is tipped on its side or is upside down; more often there is only subtle change in eye movements on optokinetic stimulation. Epileptic activation of this area induces vertigo or a sense of disequilibrium. As pointed out in Chap. 15, pure vertiginous epilepsy does occur but is a rarity, and if vertigo precedes a seizure, it is usually momentary and quickly submerged in other components of the seizure.

**Disturbances of Time Perception** In a temporal lobe seizure originating on either side, time may seem to stand still or to pass with great speed. On recovery from such a seizure, the patient, having lost all sense of time, may repeatedly look at the clock. Assal and Bindschaedler have reported an extraordinary abnormality of time sense in which the patient invariably placed the day and date 3 days ahead of the actual ones. There had been aphasia from a left hemispherical stroke years before, but the impairment of time sense occurred only after a left temporal stroke that also produced cortical deafness.

Certainly the most common disruptions of the sense of time occur as part of confusional states of any type. The usual tendency is for the patient to report the current date as an earlier one, much less often as a later one. Characteristically in this situation the responses vary from one examination to the next. The patient with a Korsakoff amnesic state is unable to place events in their proper time relationships, presumably because of failure of retentive memory, a function assignable to the medial temporal lobes.

**Disturbances of Smell and Taste** (See also Chap. 12) The central anatomy and physiology of these two senses have been elusive. Brodal concluded that the hippocampus was not involved. However, seizure foci in the medial part of the temporal lobe (in the region of the uncus) often evoke olfactory hallucinations. This type of “uncinate fit,” as originally pointed out by Jackson and Stewart, is often accompanied by a dreamy state, or, in the words of Penfield, an “intellectual aura.” The central areas identified physiologically with olfaction are the posterior orbitofrontal, subcallosal, anterior temporal, and insular cortices, i.e., the areas that mediate numerous visceral functions.

In comparison, hallucinations of taste are rare. Stimulation of the posterior insular area elicited a sensation of taste along with disturbances of alimentary function (Penfield and Faulk). There are cases in which a lesion in the medial temporal lobe caused both gustatory and olfactory hallucinations. Sometimes the patient cannot decide whether he experienced an abnormal odor, taste, or both. The anatomy and physiology of smell and taste are discussed further in Chap. 12.

**Other (Nonauditory) Syndromes** Between the hippocampal formation (on the inferomedial surface of the temporal lobe) and the primary and secondary auditory areas (Heschl’s transverse gyri
and superior temporal convolution, respectively), there is a large inferolateral expanse of temporal lobe that has only vaguely assignable integrative functions. With lesions in these parts of the dominant temporal lobe, a defect in the retrieval of words (amnesic dysnomia) has been a frequently observed abnormality. Stimulation of the posterior parts of the first and second temporal convolutions of fully conscious epileptic patients can arouse complex memories and visual and auditory images, some with strong emotional content (Penfield and Roberts).

The loss of certain visual integrative abilities, particularly face recognition (prosopagnosia), is usually assigned to lesions of the inferior occipital lobes as discussed further on, but the area implicated borders on the adjacent inferior temporal lobe as well.

Careful psychologic studies disclose a difference between the effects of dominant and nondominant partial (anterior) temporal lobectomy (Milner). With the former, there is dysnomia and impairment in the learning of material presented through the auditory sense; with the latter, there is impairment in the learning of visually presented material. In addition, about 20 percent of patients who have undergone temporal lobectomy, left or right, show a syndrome similar to that which results from lesions of the prefrontal regions. Perhaps more significant is the observation that the remainder of the cases show little or no defect in personality or behavior.

Disorders of Memory, Emotion, and Behavior Finally, attention must be drawn to the central role of the temporal lobe, notably its hippocampal and limbic parts, in memory and learning and in the emotional life of the individual. As indicated earlier, these functions and their derangements have been accorded separate chapters. Memory is discussed in Chap. 21 and the neurology of emotion and behavior in Chap. 25.

To summarize, human temporal lobe syndromes include the following:

I. Effects of unilateral disease of the dominant temporal lobe
   A. Homonymous upper quadrantanopia
   B. Wernicke’s aphasia (word-deafness—auditory verbal agnosia)
   C. Amusia (some types)
   D. Impairment in tests of verbal material presented through the auditory sense
   E. Dysnomia or amnesic aphasia
   F. Visual agnosia
   G. Occasionally amnesic (Korsakoff) syndrome

II. Effects of unilateral disease of the nondominant temporal lobe
   A. Homonymous upper quadrantanopia
   B. Inability to judge spatial relationships in some cases
   C. Impairment in tests of visually presented nonverbal material
   D. Agnosia for sounds and some qualities of music

III. Effects of disease of either temporal lobe
   A. Auditory, visual, olfactory, and gustatory hallucinations
   B. Dreamy states with uncinate seizures
   C. Emotional and behavioral changes
   D. Delirium (usually nondominant)
   E. Disturbances of time perception

IV. Effects of bilateral disease
   A. Korsakoff amnesic defect (hippocampal formations)
   B. Apathy and placidity

C. Hypermetamorphopsia (compulsion to attend to all visual stimuli), hyperorality, hypersexuality, blunted emotional reactivity (Klüver-Bucy syndrome; the full syndrome is rarely seen in man)

SYNDROMES CAUSED BY LESIONS OF THE PARIETAL LOBES

Anatomic and Physiologic Considerations

This part of the cerebrum, lying behind the central sulcus and above the sylvian fissure, is the least well demarcated (Fig. 22-7). Its posterior boundary, where it merges with the occipital lobe, is obscure, as is part of the inferior boundary, where it merges with the temporal lobe. On its medial side, the parieto-occipital sulcus marks the posterior border, which is completed by extending the line of the sulcus downward to the preoccipital notch on the inferior border of the hemisphere. Within the parietal lobe, there are two important sulci: the postcentral sulcus, which forms the posterior boundary of the somesthetic cortex, and the interparietal sulcus, which runs anteroposteriorly from the middle of the posterior central sulcus and separates the mass of the parietal lobe into superior and inferior lobules (Figs. 22-2 and 22-7). The inferior parietal lobule is composed of the supramarginal gyrus (Brodmann’s area 40) and the angular gyrus (area 39). The architecture of the postcentral convolution is typical of all primary receptive areas (homotypical granular cortex). The rest of the parietal lobe resembles the association cortex, both unimodal and heteromodal, of the frontal and temporal lobes.

The superior and inferior parietal lobules and adjacent parts of the temporal and occipital lobes are relatively much larger in humans than in any of the other primates and are relatively slow in attaining their fully functional state (beyond the seventh year of age). This area of heteromodal cortex has large fiber connections with the frontal, occipital, and temporal lobes of the same hemisphere and, through the middle part of the corpus callosum, with corresponding parts of the opposite hemisphere.

The postcentral gyrus, or primary somatosensory cortex, receives most of its afferent connections from the ventroposterior thalamic nucleus, which is the terminus of the ascending somatosensory pathways. The contralateral half of the body is represented somatotopically in this gyrus on the posterior bank of the rolandic sulcus. It has been shown in the macaque that spindle afferents project to area 3a, cutaneous afferents to areas 3b and 1, and joint afferents to area 2 (Kaas). Stimulation of the postcentral gyrus elicits a numb, tingling sensation and sense of movement. Penfield remarked that rarely are these tactile illusions accompanied by pain, warmth, or cold. Stimulation of the motor cortex may produce similar sensations, as do discharging seizure foci from these regions. The primary sensory cortex projects to the superior parietal lobule (area 5), which is the somatosensory association cortex. Some parts of areas 1, 3, and 5 (except the hand and foot representations) probably connect, via the corpus callosum, with the opposite somatosensory cortex. There is some uncertainty as to whether area 7 (which lies posterior to area 5) is unimodal somatosensory or heteromodal visual and somatosensory; certainly it receives a large contingent of fibers from the occipital lobe.

In humans, electrical stimulation of the cortex of the superior and inferior parietal lobules evokes no specific motor or sensory
effects. Overlapping here, however, are the tertiary zones for vision, hearing, and somatic sensation, the supramodal integration of which is essential to our awareness of space and person and certain aspects of language and calculation, as described below.

The parietal lobe is supplied by the middle cerebral artery, the inferior and superior divisions supplying the inferior and superior lobules, respectively, although the demarcation between the areas of supply of these two divisions is found to be variable.

Despite Critchley’s pessimistic prediction that establishing a formula of normal parietal function will prove to be a “vain and meaningless pursuit,” our concepts of the activities of this part of the brain are now assuming some degree of order. There is little reason to doubt that the anterior parietal cortex contains the mechanisms for tactile percepts. Discriminative tactile functions, listed below, are organized in the more posterior, secondary sensory areas. But the greater part of the parietal lobe functions as a center for integrating somatosensory with visual and auditory information in order to construct an awareness of one’s own body (body schema) and its relation to extrapersonal space. Connections with the frontal and occipital lobes provide the necessary proprioceptive and visual information for movement of the body and manipulation of objects and for certain constructional activities (constructional apraxia). Impairment of these functions implicates the parietal lobes, more clearly the nondominant one (on the right). Also, the conceptual patterns on which complex voluntary motor acts are executed depend on the integrity of the parietal lobes, particularly the dominant one. Defects in this region give rise to ideomotor apraxia, as discussed further on. The understanding of spoken and written words is partly a function of the supramarginal and angular gyri of the dominant parietal lobe as elaborated in Chap. 23. The recognition and utilization of numbers, arithmetic principles, and calculation, which have important spatial attributes, are other functions integrated principally through these structures.

Clinical Effects of Parietal Lobe Lesions

Within the brain, no other territory surpasses the parietal lobes in the rich variety of clinical phenomena exposed under conditions of disease. Our current understanding of the effects of parietal lobe disease contrasts sharply with that of the late nineteenth century, when these lobes, in the classic textbooks of Oppenheim and Gow-ers, were considered to be “silent areas.” However, the clinical manifestations of parietal lobe disease may be subtle, requiring special techniques for their elicitation; even more difficult is the interpretation of these abnormalities of function in terms of a coherent and plausible physiology and psychology.

Close to the core of the complex behavioral features that arise from lesions of the parietal lobes is the problem of agnosia. Allusion has already been made to agnosia in the discussion of lesions of the temporal lobes that affect language, and similar findings occur with lesions of the occipital lobe as discussed further on. In those contexts, the term refers to a loss of recognition of an entity that cannot be attributed to a defect in the primary sensory modality. As a result of the extension of the term agnosia to a loss of more complex integrated functions as described below, a number of intriguing deficits arise. These syndromes expose properties of the parietal lobe that have implications regarding a map of the body schema and of external topographic space, of the ability to calculate, to differentiate left from right, to write words, and other problems discussed below. The fact that apraxia, an inability to carry out a commanded task despite the retention of motor and sensory function, is also predominantly the result of parietal lobe damage, and the relationship of the apraxias to language and to each other, exposes one of the most complicated issues in behavioral neurology. The theoretical aspects of agnosia, particularly those related to the disturbances of visual processing, are discussed later in the chapter.

Cortical Sensory Syndromes The effects of a parietal lobe lesion on somatic sensation were first described by Verger and then more completely by Déjerine, in his monograph *L’agnosie corticale*, and by Head and Holmes. The latter, in their important paper of 1911, noted the close interrelationships between the thalamus and the sensory cortex. As pointed out on page 133, the parietal postcentral cortical defect is essentially one of sensory discrimination, i.e., an impairment or loss of the sense of position and passive movement and the ability to localize tactile, thermal, and noxious stimuli applied to the body surface; to distinguish objects by their size, shape, and texture (astereognosis); to recognize figures written on the skin; to distinguish between single and double contacts (two-point discrimination); and to detect the direction of movement of a tactile stimulus. In contrast, the perception of pain, touch, pressure, vibratory stimuli, and thermal stimuli is relatively intact. This type of sensory defect is sometimes referred to as “cortical,” although it can be produced just as well by lesions of the subcortical connections. Clinicoadanatomic studies indicate that parietocortical lesions that spare the postcentral gyrus produce only transient somatosensory changes or none at all (Corkin et al; Car- mon and Benton).

The question of bilateral sensory deficits as a result of lesions in only one postcentral convolution was raised by the studies of Semmes and of Corkin and their associates. In tests of pressure sensitivity, two-point discrimination, point localization, position sense, and tactile object recognition, they found bilateral disturbances in nearly half of their patients with unilateral lesions, but the deficits were always more severe contralaterally and mainly in the hand. These disturbances of discriminative sensation and the subject of tactile agnosia are discussed more fully in Chap. 9.

Déjerine and Mouzon described another parietal sensory syndrome in which touch, pressure, pain, thermal, vibratory, and position sense are all lost on one side of the body or in a limb. This syndrome, more typically the result of a thalamic lesion, may also occur with large, acute lesions (infarcts, hemorrhages) in the central and subcortical white matter of the contralateral parietal lobe; in the latter case these symptoms recede in time, leaving more subtle defects in sensory discrimination. Smaller lesions, particularly ones that result from a glancing blow to the skull or a small infarct or hemorrhage, may cause a defect in cutaneous-kinesthetic perception in a discrete part of a limb, e.g., the ulnar or radial half of the hand and forearm; these cerebral lesions may mimic a peripheral nerve or root lesion (Dodge and Meirowsky). Also, a pseu-thalamo-memorial pain syndrome on the side deprived of sensation by a parietal lesion has been described (Biemond). In a series of 12 such patients described by Michel and colleagues, burning or constrictive pain, identical to the thalamic pain syndrome (page 141), resulted from vascular lesions restricted to the cortex. The discomfort involved the entire half of the body or matched the region of cortical hyposthesia; in a few cases the symptoms were paroxysmal.

Head and Holmes drew attention to a number of interesting points about patients with parietal sensory defects—the easy fatigability of their sensory perceptions; the inconsistency of responses to painful and tactile stimuli; the difficulty in distinguishing more
than one contact at a time; the disregard of stimuli on the affected side when the healthy side is stimulated simultaneously (tactile inattention or extinction); the tendency of superficial pain sensations to outlast the stimulus and to be hyperesthetic; and the occurrence of hallucinations of touch. Of these, the testing of sensory extinction by the presentation of two tactile stimuli simultaneously on both sides of the body has become a component of the routine neurologic examination for parietal lesions.

With anterior parietal lobe lesions there is often an associated mild hemiparesis, since this portion of the parietal lobe contributes a considerable number of fibers to the corticospinal tract. Or, more often, there is only a poverty of movement or a weak effort of the opposite side in the absence of somatic neglect. The affected limbs, if involved with this apparent weakness, tend to remain hyponic and the musculature may undergo atrophy of a degree not explained by inactivity alone. In some cases, as noted below, there is clumsiness in reaching for and grasping an object under visual guidance (optic ataxia), and exceptionally, at some phase in recovery from the hemisensory deficit, there is incoordination of movement and intention tremor of the contralateral arm and leg, simulating a cerebellar syndrome. While relatively rare, it is authenticated by our own case observations. With parietal lesions, the arm and hand may sometimes be held in a fixed dystonic posture.

The Asomatognosias The term asomatognosia denotes the inability to recognize part of one’s body. The idea that visual and tactile sensory information is synthesized during development into a body schema or image (perception of one’s body and the relations of bodily parts to one another) was first clearly formulated by Pick and elaborated by Brain. Long before their time, however, it was suggested that such information was the basis of our emerging awareness of ourselves as persons, and philosophers had assumed that this comes about by the constant interplay between perceops of ourselves and of the surrounding world.

The formation of the body schema is thought to be based on the constant influx and storage of sensations from our bodies as we move about; hence, motor activity is important in its development. Always, however, a sense of extrapersonal space is central to this activity, and this depends upon visual and labyrinthine stimulation. The mechanisms upon which these perceptions depend are best appreciated by studying their derangements in the course of neurologic disease of the parietal lobes.

Anosognosia (Unilateral Asomatognosia; Anton-Babinski Syndrome) and Hemispatial Neglect The observation that a patient with a dense hemiplegia, usually of the left side, may be indifferent to the paralysis or unaware of it was first made by Anton; later, Babinski named this disorder anosognosia. It may express itself in several ways: The patient may act as if nothing were the matter. If asked to raise the paralyzed arm, he may raise the intact one or do nothing at all. If asked whether the paralyzed arm has been moved, the patient may say “yes.” If the fact that the arm has not been moved is pointed out, the patient may admit that the arm is slightly weak. If it is paralyzed, the patient may deny that this is so or offer an excuse: “My shoulder hurts.” If asked why the paralysis went unnoticed, the response may be, “I’m not a doctor.” Some patients report that they feel as though their left side had disappeared, and when shown the paralyzed arm, they may deny it is theirs and assert that it belongs to someone else or even take hold of it and fling it aside. This mental derangement, which Hughlings Jackson referred to as “a kind of imbecility,” obviously includes a somatosensory defect that encompasses loss of the stored body schema as well as a conceptual negation of paralysis and a disturbed visual perception and neglect of half of the body. It should be pointed out that the allied symptoms of loss of body scheme and the lack of appreciation of a left hemiplegia are separable, some patients displaying only one feature. The term anosognosia for hemiplegia has been used to describe the latter phenomenon.

The lesion responsible for the various forms of one-sided asomatognosia lies in the cortex and white matter of the superior parietal lobule but may extend variably into the postcentral gyrus, frontal motor areas, and temporal and occipital lobes, accounting for some of the associated abnormalities described below. Rarely, a deep lesion of the ventrolateral thalamus and the juxtaposed white matter of the parietal lobe will produce a similar contralateral neglect. Unilateral asomatognosia is seven times as frequent with right (nondominant) parietal lesions as with left-sided ones, according to Hécaen’s statistics. The apparent infrequency of rightsided symptoms is attributable in part but not entirely to their obfuscation by an associated aphasia.

Anosognosia is usually associated with a number of additional abnormalities. Often there is a blunted emotionality. The patient looks dull, is inattentive and apathetic, and shows varying degrees of general confusion. There may be an indifference to performance failure, a feeling that something is missing, visual and tactile illusions when sensing the paralyzed part, hallucinations of movement, and allochiria (one-sided stimuli are felt on the other side).

Another common group of parietal symptoms consists of neglect of one side of the body in dressing and grooming, recognition only on the intact side of bilaterally and simultaneously presented stimuli (sensory extinction) as mentioned above, deviation of head and eyes to the side of the lesion, and torsion of the body in the same direction (failure of directed attention to the body and to extrapersonal space on the side opposite the lesion). The patient may fail to shave one side of the face, apply lipstick or comb the hair only on one side, or find it impossible to put on eyeglasses, insert dentures, or put on a shirt or gown when one sleeve has been turned inside out (the problem dressing, when it is apparent on both sides of the body, is more of a dressing apraxia).

Unilateral spatial neglect is brought out by having the patient bisect a line, draw a daisy or a clock, or name all the objects in the room. Homonymous hemianopia and varying degrees of hemiparesis may or may not be present and interfere with the interpretation of the lack of application on the left side of the drawing.

A special type of spatial neglect is reflected in the patient’s inability to reproduce geometric figures (constructional apraxia). A number of tests have been devised to elicit these disturbances, such as indicating the time by placement of the hands on a clock, drawing a map, copying a complex figure, reproducing stick-pattern constructions and block designs, making three-dimensional constructions, and reconstructing puzzles.

According to Denny-Brown and Banker, the basic disturbance in such cases is an inability to summate a series of “spatial impressions”—tactile, kinesthetic, visual, or auditory—a defect they referred to as amorphosynthesis. In their view, imperception or neglect of one side of the body and of extrapersonal space is the essential feature and represents the full extent of the disturbance, which in lesser degree consists only of tactile and visual extinction. They make the additional points that the disorder of spatial summation is strictly contralateral to the damaged parietal lobe, right or left, and must be distinguished from a true agnosia, which is a conceptual disorder and involves both sides of the body and extra-
personal space as a result of damage to one (the dominant) hemisphere. More recent observations indicate that patients with right parietal lesions show variable but lesser elements of ipsilateral neglect in addition to the striking degree of contralateral neglect, suggesting that, in respect to spatial attention, the right parietal lobe is truly dominant (Weintraub and Mesulam).

A clever observation of Bisiach and Luzzatti has suggested that the loss of attention to one side of the environment extends to the mental representation of space. Their patient with a right parietal lesion was asked to describe from memory the buildings lining the Piazza del Duomo, first as if seen from one corner of the piazza and then from the opposite corner. In each instance the description omitted the left side of the piazza from the observer’s perspective. This has similarities to the topographicalagnosia described further on.

Perhaps another aspect of parietal lobe physiology, revealed by human disease, is the loss of exploratory and orienting behavior with the contralateral arm and even a tendency to avoid tactile stimuli. Mori and Yamadori call this rejection behavior. Denny-Brown and Chambers attribute the released grasping and exploring that follow frontal lobe lesions to a disinhibition of inherent parietal lobe automatisms, but we have no way of confirming this. It is of interest that demented patients with prominent grasp reflexes tend not to grasp parts of their own bodies unless there has been a parietal lesion, in which case there may be “self-grasping” of the forearm opposite the lesion (Ropper).

Conventional treatments for hemispatial neglect use prismatic glasses and training in visual exploration of the left side. Of some interest has been an approach that demonstrates improvement by the application of vibratory stimulation to the right side of the neck as reported by Karnath and colleagues or of the ipsilateral labyrinth by caloric or electrical means (a similar treatment has been successful in some cases of dystonic torticollis, see Chap. 6).

Gerstmann Syndrome This syndrome provides the most striking example of what might be viewed as a bilateral asomatognosia and is due to a left or dominant parietal lesion. The characteristic features are inability to designate or name the different fingers of the two hands (finger agnosia), confusion of the right and left sides of the body, and inability to calculate (dyscalculia) and to write (dysgraphia). One or more of these manifestations may be associated with word-blindness (alexia) and homonymous hemianopia or a lower quadrantanopia, of which the patient is usually unaware. The lesion is in the inferior parietal lobule (below the interparietal sulcus), particularly the angular gyrus or subjacent white matter of the left hemisphere.

There has been a dispute as to whether the four main elements of the Gerstmann syndrome have a common basis or only an association. Benton states that they occur together in a parietal lesion no more often than do constructional apraxia, alexia, and loss of visual memory and that every combination of these symptoms and those of the Gerstmann syndrome occurs with equal frequency in parietal lobe disease. Others, including the authors, tend to disagree and believe that right-left confusion, digital agnosia, agraphia, and acalculia have special significance, possibly being linked through a unitary defect in spatial orientation of fingers, body sides, and numbers. The relationship between the fingers and the ability to enumerate is especially intriguing and relates to other arithmetic difficulties, discussed below.

Dyscalculia has attracted little critical attention, perhaps because it occurs most often as a by-product of aphasia and an inability of the patient to appreciate numerical language. Primary dyscalculia is usually associated with the other elements of the Gerstmann syndrome. Computational difficulty may also be part of the more complex visuospatial abnormality of the nondominant parietal lobe; there is then difficulty in the placing of numbers in specific spatial relationships while calculating. In such cases, there is no difficulty in reading or writing the numbers or in describing the rules governing the calculation, but the computation cannot be accomplished correctly with pencil and paper. Hécaen has made a distinction between this type of anarithmetic and dyscalculia; in the latter, the process of calculation alone has been disturbed; in the former, there is an inability to manipulate numbers and to appreciate their ordinal relationships. Recognition and reproduction of numbers are intact in both. An analysis of how computation goes awry in each individual case is therefore required.

Lesions of the superior parietal lobule may interfere with voluntary movement of the opposite limbs, particularly the arm, as pointed out by Holmes. In reaching for a visually presented target in the contralateral visual field and to a lesser extent in the ipsilateral field, the movement is misdirected and dysmetric (the distance to the target is misjudged). This disorder of movement, mentioned above in the general discussion of parietal signs and sometimes referred to as optic ataxia, resembles cerebellar ataxia and may be explained by the fact that cortical areas 7 and 5 receive visual projections from the parasagittal areas and proprioceptive ones from the cerebellum, both of which are integrated in the multimodal parietal cortex. Areas 5 and 7, in turn, project to frontal areas 6, 8, and 9, where oculoc scanning and reaching are coordinated.

Ideomotor and Ideational Apraxia As discussed extensively in Chap. 3, patients with parietal lesions of the dominant hemisphere who exhibit no defects in motor or sensory function lose the ability to perform learned motor skills on command or by imitation. They can no longer use common implements and tools, either in relation to their bodies (e.g., brushing teeth, combing hair) or in relation to objects in the environment (e.g., a doorknob or hammer). The patient holds the implement awkwardly or seems at a loss to begin the act. It is as though the patient had forgotten the sequences of learned movements. The effects are bilateral. It is of interest that, in both agraphia and acalculia, the motor defect is intertwined with some of these agnostic defects; hence the term apractognosia seems appropriate for the combined problem.

From the above descriptions, it is evident that the left and right parietal lobes function differently. The most obvious difference, of course, is that language and arithmetical functions are centered in the left hemisphere. It is hardly surprising, therefore, that verbally mediated or verbally associated spatial and praxic functions are more affected with left-sided than with right-sided lesions. It must also be realized that language function involves cross-modal connections and is central to all cognitive functions. Hence cross-modal matching tasks (auditory-visual, visual-auditory, visual-tactile, tactile-visual, auditory-tactile, etc.) are most clearly impaired with lesions of the dominant hemisphere. Such patients can read and understand spoken words but cannot grasp the meaning of a sentence if it contains elements of relationship (e.g., “the mother’s daughter” versus “the daughter’s mother,” “the father’s brother’s son,” “Jane’s complexion is lighter than Marjorie’s but darker than her sister’s”). There are similar difficulties with calculation, as just described. The recognition and naming of parts of the body and the distinction of right from left and up from down are learned, verbally mediated spatial concepts that are disturbed by lesions in the dominant parietal lobe.
Visual Disorders with Parietal Lesions  A lesion deep to the inferior part of the parietal lobe, at its junction with the temporal lobe, involves the geniculocalcarine radiations and result in an incongruous homonymous hemianopia or an inferior quadrantanopia; but just as often, in practice, the defect is complete or almost complete and congruous. An alexia or components of the Gerstmann syndrome may be associated. If the lesion is small and predominantly cortical, optokinetic nystagmus is usually retained; with deep lesions, it is abolished, with the target moving ipsilaterally (see Chap. 14).

From time to time, severe left-sided visual neglect results from a lesion in the right angular gyrus (see Mort and colleagues). The problem in its more severe forms is evident from casual observation of the patient’s behavior or in drawings made by the patient which omit features on the left side; but here a more pervasive syndrome of hemispatial neglect, discussed earlier, may be responsible. In keeping with others, the aforementioned authors have confirmed that visual neglect can occur after focal lesions in the posterior medial temporal lobe (supplied by the posterior cerebral artery, in contrast to the middle cerebral artery supply of the angular gyrus of the inferior parietal lobule); however, they also maintain, on the basis of MRI studies in stroke patients, that lesions in the superior temporal lobe, previously implicated, are not responsible for visual neglect.

With posterior parietal lesions, as noted by Holmes and Horrax, there are deficits in localization of visual stimuli, inability to compare the sizes of objects, failure to avoid objects when walking, inability to count objects, disturbances in smooth-pursuit eye movements, and loss of stereoscopic vision. Cogan observed that the eyes may deviate away from the lesion on forced lid closure, a “spasticity of conjugate gaze”; we have been able to elicit this sign only rarely.

Visual Disorientation and Disorders of Spatial (Topographic) Localization  Spatial orientation depends on the integration of visual, tactile, and kinesthetic perceptions, but there are instances in which the defect in visual perception predominates. Patients with this disorder are unable to orient themselves in an abstract spatial setting (topographicalagnosia). Such patients cannot draw the floor plan of their house or a map of their town—or of the United States—and cannot describe a familiar route, as from home to work, for example, or find their way in familiar surroundings. In brief, such patients have lost topographic memory. This disorder is almost invariably caused by lesions in the dorsal convexity of the right parietal lobe, and it is separable from the anosognosia discussed earlier.

A common and striking disorder of motor behavior of the eyelids is seen in many patients with large acute lesions of the right parietal lobe. Its mildest form is a disinclination to open the lids when spoken to. This gives the erroneous impression that the patient is drowsy or stuporous, but it will be found that a quick reply is given to whispered questions. In more severe cases, the lids are held shut and opening is strongly resisted, to the point of making an examination of the pupils and fundi impossible.

Auditory Neglect  This defect in appreciation of the left side of the environment is less apparent than is visual neglect, but it is no less striking when it occurs. Many patients with acute right parietal lesions are initially unresponsive to voices or noises on the left side, but the syndrome is rarely persistent. Special tests, however, demonstrate, in many of these patients, a displacement of the direction of the perceived origin of sounds toward the left. This defect is separable from visual agnosia (see De Renzi et al); curiously, it may be worsened by the introduction of visual cues. Subtle differences between the allocation of spatial attention to sound (auditory neglect) and a distortion in its localization may be found in different cases, but the main lesion usually lies in the right superior lobule, and the same bias for left hemispheric lesions applies as for visual inattention.

In summary, the effects of disease of the parietal lobes are as follows:

I. Effects of unilateral disease of the parietal lobe, right or left
   A. Corticosenso syndrome and sensory extinction (or total hemianesthesia with large acute lesions of white matter)
   B. Mild hemiparesis (variable), unilateral muscular atrophy in children, hypotonia, poverty of movement, hemiataxia (all seen only occasionally)
   C. Homonymous hemianopia or inferior quadrantanopia (incongruent or congruent) or visual inattention
   D. Abolition of optokinetic nystagmus with target moving toward side of the lesion
   E. Neglect of the opposite side of external space (far more prominent with lesions of the right parietal lobe—see below)

II. Effects of unilateral disease of the dominant (left) parietal lobe (in right-handed and most left-handed patients)—additional phenomena include
   A. Disorders of language (especially alexia)
   B. Gerstmann syndrome (dysgraphia, dyscalculia, finger agnosia, right-left confusion)
   C. Tactile agnosia (bimanual astereognosis)
   D. Bilateral ideomotor and ideational apraxia (see Chap. 3)

III. Effects of unilateral disease of the nondominant (right) parietal lobe
   A. Visuospatial disorders
   B. Topographic memory loss
   C. Anosognosia, dressing and constructional apraxias (these disorders may occur with lesions of either hemisphere but one observed more frequently and are of greater severity with lesions of the nondominant one)
   D. Confusion
   E. Tendency to keep the eyes closed, resist lid opening, and blepharospasm

IV. Effects of bilateral disease of the parietal lobes
   A. Visual spatial imperception, spatial disorientation, and complete or partial Balint syndrome (optic apraxia, described below)

With all these parietal syndromes, if the disease is sufficiently extensive, there may be a reduction in the capacity to think clearly as well as inattentiveness and slightly impaired memory.

It is still not possible to present an all-embracing formula of parietal lobe function. It does seem reasonably certain that, in addition to the perception of somatosensory impulses (postcentral gyrus), the parietal lobe participates in the integration of all sensory data, especially those that provide an awareness of one’s body as well as a percept of one’s surroundings and of the relation of one’s body to extrapersonal space and of objects in the environment to each other. In this respect, the parietal lobe may be regarded as a
special high-order sensory organ—the locus of transmodal (inter-
sensory) integrations, particularly tactile and visual ones, which are
the basis of our concepts of spatial relations. In this way, parietal
lesions cause disorders of specific types of self-consciousness or
self-awareness that are tied to sensory modalities, but they do not
do so in the fundamental way that results from lesions of the tem-
poral lobe.

Useful references on parietal function include Critchley’s
monograph on the parietal lobes and the chapter by Botez et al in
the Handbook of Clinical Neurology.

SYNDROMES CAUSED BY
LESIONS OF THE OCCIPITAL
LOBES
Anatomic and Physiologic
Considerations

The occipital lobes are the termini of the geniculocalcarine path-
ways and are essential for visual perception and recognition. This
part of the brain has a large medial surface and somewhat smaller
lateral and inferior surfaces (Fig. 22-7). The parieto-occipital fusi-
urse creates an obvious medial boundary with the parietal lobe, but
laterally it merges with the parietal and temporal lobes. The large
calcarine fissure courses in an anteroposterior direction from the
pole of the occipital lobe to the splenium of the corpus callosum;
area 17, the primary visual receptive cortex, lies on its banks (Fig.
22-2). This area is typical homotypical cortex but is unique in that
its fourth receptive layer is divided into two granular laminae
by a greatly thickened band of myelinated fibers, the external band
of Baillarger. This stripe, also called the line or band of Gennari,
is grossly visible and has given this area its name— striate cortex.
The largest part of area 17 is the terminus of the retinal macular
fibers via the lateral geniculate (see Fig. 13-2). The parastriate cor-
tex (areas 18 and 19) lacks the line of Gennari and resembles the
granular unimodal association cortex of the rest of similar areas in
the cerebrum. Area 17 contains cells that are activated by the homo-
lateral geniculocalcine pathway (corresponding, of course, exclu-
sively to the contralateral visual field); these cells are intercon-
ected and project also to cells in areas 18 and 19. The latter are
connected with one another and with the angular gyri, lateral and
medial temporal gyri, frontal motor areas, limbic and paralimbic
areas, and corresponding areas of the opposite hemisphere through
the posterior third (splenium) of the corpus callosum.

The occipital lobes are supplied almost exclusively by the
posterior cerebral arteries and their branches, either directly in most
individuals or through an embryologically persistent branch of the
internal carotid arteries (“fetal” posterior cerebral artery). A small
area of the occipital pole receives blood supply from the inferior
division of the middle cerebral artery. (This assumes importance
in the clinical finding of “macular sparing,” discussed on page
218.)

The connections among these several areas in the occipital
lobe are complicated, and the old notion that area 17 is activated
by the lateral geniculate neurons and that this activity is then trans-
ferred and elaborated in areas 18 and 19 is surely not complete.
Actually, four or five occipital receptive fields are activated by
lateral geniculate neurons, and fibers from area 17 project to ap-
proximately 20 other visual areas, of which only 5 are well iden-
tified. These extrastriate visual areas lie in the lingula and posterior
regions of the occipital lobes. Monkeys with bilateral lesions in the
temporal visual zones lose the ability to identify objects; with pos-
terior parietal lesions, there is loss of ability to locate objects. And,
as Hubel and Wiesel have shown, the response patterns of neurons
in both occipital lobes to edges and moving visual stimuli, to on-
and-off effects of light, and to colors are much different from what
was originally supposed. Hence, form, location, color, and move-
ment each have separate localizable mechanisms. The monographs
of Polyak and of Miller contain detailed information about the anat-
omy and physiology of this part of the brain.

Clinical Effects of Occipital Lobe
Lesions

Visual Field Defects  The most familiar clinical abnormality re-
sulting from a lesion of one occipital lobe, homonymous hemiano-
pia, has already been discussed in Chap. 13. Extensive destruction
abolishes all vision in the corresponding half of each visual field.
With a neoplastic lesion that eventually involves the entire striate
region, the field defect may extend from the periphery toward the
center, and loss of color vision (hemiachromatopsia) often precedes
loss of black and white. Lesions that destroy only part of the striate
cortex on one side yield characteristic field defects that accurately
indicate the loci of the lesions. A lesion confined to the pole of the
occipital lobe results in a central hemianopic defect that splits the
macula and leaves the peripheral fields intact. This observation
indicates that half of each macula is unilaterally represented and
that the maculae may be involved (split) in hemianopia. Bilateral
lesions of the occipital poles, as in embolism of the posterior ce-
rebral arteries, result in bilateral central hemianopias. Unilateral
quadrant defects and altitudinal field defects due to striate lesions
indicate that the cortex on one side, above or below the calcarine
fissure, is damaged. The cortex below the fissure is the terminus of
fibers from the lower half of the retina; the resulting field defect is
in the upper quadrant, and vice versa. Most bilateral altitudinal
defects are traceable to incomplete bilateral occipital lesions (cortex
or terminal parts of geniculocalcine pathways). Head and Holmes
described several such cases due to gunshot wounds; embolic or
thrombotic infarction is now the common cause.

As indicated in Chap. 13, the homonymous hemianopia that
results from ablation of one occipital lobe is not absolute. In mon-
keys, visuospatial orientation and the capacity to reach for moving
objects in the defective field are preserved (Denny-Brown and
Chambers). In humans also, flashing light and moving objects can
sometimes be seen in the blind field even without the patient’s full
awareness. Weiskrantz and colleagues have referred to these pre-
served functions as blindsisms or blindsight. It is useful as a practical
manner to note that the optokinetic responses are usually spared in
hemianopic deficits of occipital origin, but our experience suggests
that this is not always the case in occipital strokes, perhaps in part
because of adjacent edema or hemorrhage caused by infarction.

Cortical Blindness  With bilateral lesions of the occipital lobes
(destruction of area 17 of both hemispheres), there is a loss of sight
and a loss of reflex closure of the eyelids to a bright light or threat.
The degree of blindness may be equivalent to that which follows
severing of the optic nerves. The pupillary light reflexes are pre-
served, since they depend upon visual fibers that terminate in the
midbrain, short of the geniculate bodies (see Fig. 14-6). Usually
no changes are detectable in the retinas, though van Buren has
described slight optic atrophy in monkeys long after occipital abla-
tions. The eyes are still able to move through a full range, but
Visual Anosagnosia (Anton Syndrome) The main characteristic of this disorder is the denial of blindness by a patient who obviously cannot see. The patient acts as though he could see, and in attempting to walk, collides with objects, even to the point of injury. He may offer excuses for his difficulties: “I lost my glasses,” “The light is dim,” etc., or he may even evince indifference to his loss of sight. The lesions in cases of negation of blindness extend beyond the striate cortex to involve the visual association areas.

Rarely, the opposite condition arises: a patient is able to see small objects but claims to be blind. This individual walks about avoiding obstacles, picks up crumbs or pills from the table, and catches a small ball thrown from a distance. Damasio suggests that this might be a type of visual disorientation but with sufficient residual visual information to guide the hand, and that the lesion will be in the visual association areas superior to the calcarine cortex.

Visual Illusions (Metamorphopsias) These may present as distortions of form, size, movement, or color. In a group of 83 patients with visual perceptual abnormalities, Hécaen found that 71 fell under one of four headings: deformation of the image, change in size, illusion of movement, or a combination of all three. Illusions of these types have been reported with lesions confined to the occipital lobes but are more frequently due to shared occipitoparietal or occipitotemporal lesions; they are therefore also considered in earlier sections of this chapter as well as in Chaps. 13 and 16. The right hemisphere appears to be involved more often than the left. Illusions of movement occur more frequently with posterior temporal lesions or seizures, polyopia (one object appearing as two or more objects) more frequently with occipital lesions (it also occurs in hysteria), and palinopia (perseveration of visual images) with both posterior parietal and occipital lesions. Visual field defects are present in many of the cases. In all these conditions the anatomic correlates are imprecise.

It is likely that an element of cortical vestibular disorder underlies the metamorphosis of parieto-occipital lesions. The vestibular and proprioceptive systems are represented in the parietal lobes of each side and the lesions there are probably responsible for misperceptions of movement and spatial relations. The illusion of tilting of the environment or upside-down vision is known to occur with parieto-occipital lesions but occurs more often with abnormalities of the vestibular system.

Visual Hallucinations These phenomena may be elementary or complex, and both types have sensory as well as cognitive aspects. Elementary (or unformed) hallucinations include flashes of light, colors, luminous points, stars, multiple lights (like candles), and geometric forms (circles, squares, and hexagons). They may be stationary or moving (zigzag, oscillations, vibrations, or pulsations). They are much the same as the effects that Foerster and Penfield obtained by stimulating the calcarine cortex in a conscious patient. Complex (formed) hallucinations include objects, persons, or animals and infrequently, more complete scenes. They are indicative of lesions in the visual association areas or their connections with the temporal lobes. They may be of natural size, lilliputian, or grossly enlarged. With hemianopia, they appear in the defective field or move from the intact field toward the hemianopic one. The patient may realize that the hallucinations are false experiences or may be convinced of their reality. Since the patient’s response is usually in accord with the nature of the hallucination, he may react with fear to a threatening vision or casually if its content is benign.

The clinical setting for the occurrence of visual hallucinations varies. The simplest black-and-white moving scintillations are part of migraine. Others, some colored, occur as a seizure aura. Often they are associated with a homonymous hemianopia, as already indicated. Frequently they are part of a confusional state or delirium (Chap. 20). Similar phenomena may occur as part of hypnologic hallucinations in the narcolepsy-cataplexy syndrome. In the “peduncular hallucinosis” of Lhermitte, the hallucinations are purely visual, appear natural in form and color—sometimes in pastels, move about as in an animated cartoon, and are considered by the patient to be unreal, abnormal phenomena (preserved insight). Ischemia in the territories of the posterior cerebral arteries is the usual cause. In our material, hallucinosis of this type (erroneously called “peduncular” insofar as that term refers to the cerebral peduncle) has been associated mainly with high mesencephalic ischemia, which obviously may also implicate the occipital lobes. As indicated above, the hallucinations in this disorder are purely visual; if hallucinations are polymodal, the lesion is always in the occipitotemporal parts of the cerebrum.

A special syndrome of ophthalmopathic hallucinations occurs in the blind person. The visual images may be of elementary or complex type, usually of people or animals, and are polychromatic (vivid colors). They may occupy all of the visual field (in the totally blind person) in the field of one eye. Moving the eyes or closing the affected eye has variable effects, sometimes abolishing the hallucinations. A similar phenomenon in elderly patients with partially impaired vision has been called the syndrome of Charles Bonnet.
following his description of visual hallucinations in a “sane” person. The topic of senile hallucinosis has been reviewed by Gold and Rabin, and 60 such patients were reported in detail by Teunisse and colleagues. The latter authors found that 11 percent of older persons with reduced vision experienced these phenomena at one time or another. In the majority of their cases the hallucinations lacked any personal meaning and were not distressing, but the patients were greatly relieved to hear that they did not have mental disease. Curiously, there are reports of improvement in the symptoms with the use of anticonvulsants such as gabapentin (Paulig and Mentrup). Further comments are to be found on page 220.

It has been traditionally taught that the lesions responsible for visual hallucinations, if identifiable, are situated in the occipital lobe or posterior part of the temporal lobe and that elementary hallucinations have their origin in the occipital cortex and complex ones, in the temporal cortex. However, the opposite may pertain; in some cases, formed hallucinations are related to lesions of the occipital lobe and unformed ones to lesions of the temporal lobe (Weinberger and Grant). Also, as emphasized by these authors, lesions that give rise to visual hallucinations, simple or elaborate, need not be confined to central nervous structures but may be caused by lesions at every level of the neuro-optic apparatus (retina, optic nerve, chiasm, etc.).

The hallucinatory phenomena of delirium are nonlocalizable, as pointed out in Chap. 20, but sometimes the evidence points to an origin in the temporal lobe.

The Visual Agnosias

Visual Object Agnosia This rare condition, first described by Lissauer in 1890, consists of a failure to name and indicate the use of a seen object by spoken or written word or by gesture. The patient cannot even tell the generic class of the object presented. Visual acuity is intact, the mind is clear, and the patient is not aphasic—conditions requisite for the diagnosis of agnosia. If the object is palpated, it is recognized at once, and it can also be identified by smell or sound if it has an odor or makes a noise. Moving the object or placing it in its customary surroundings facilitates recognition. In most reported instances of object agnosia, the patient retains normal visual acuity but cannot identify, match, or name objects presented in any part of the visual fields; if misnamed, the object is used in a fashion that reflects the incorrect perception.Amazingly, one encounters patients who have lost the capacity to recognize only one class of objects—e.g., animals or vegetables—suggesting that, in the human, stored information is grouped and classified in a way that is necessary for visual perception (we are unable to corroborate this from our own material). Lissauer conceived of visual object recognition as consisting of two distinct processes—the construction of a perceptual representation from vision (apprecitation) and the mapping of this perceptual representation onto stored percepts or engrams of the object’s functions and associations—and he proposed that impairment of either of these processes could give rise to a defect in visual object recognition.

As indicated in Chap. 13, visual object agnosia is usually associated with visual verbal agnosia (alexia) and homonymous hemianopia. Prosopagnosia (the inability to identify faces; see further on) is also present in most cases. The underlying lesions are usually bilateral, although McCarthy and Warrington have related a case to a restricted lesion of the left occipitotemporal region (by MR). Two of our patients with visual object agnosia had an incomplete amnesic syndrome from a left-sided inferior occipital and mediotemporal infarction, reflecting a proximal occlusion of the posterior cerebral artery.

Simultanagnosia Wolpert described a patient who demonstrated a “spelling dyslexia” (an inability to read all but the shortest words, spelled out letter by letter) and a failure to perceive simultaneously all the elements of a scene and to properly interpret the scene. In the framework of gestalt psychology, the patient could recognize the parts but not the whole. A cognitive defect of synthesis of the visual impressions was thought to be the basis of this condition, which Wolpert called simultanagnosia (a term that appears often in discussion). Some patients with this disorder have a right homonymous hemianopia; in others, the visual fields are full but there is one-sided extinction when tested with double simultaneous stimulation. This is part of the Balint syndrome (see below), the other components of which are faulty visual scanning (ocular apraxia) and visual reaching (optic ataxia), suggesting that perhaps a fault in ocular scanning might underlie all the defects. Through tachistoscopic testing, Kinsbourne and Warrington found that reducing the time of stimulus exposure permits single objects to be perceived, but not two objects. Rizzo and Robin have proposed that the primary defect is in sustained attention to incoming visuospatial information. Nielsen has attributed this disorder to a lesion of the inferolateral part of the dominant occipital lobe (area 18). In a patient who presented with an isolated “spelling dyslexia” and simultanagnosia, Kinsbourne and Warrington found the lesion to be localized within the inferior part of the left occipital lobe. In other instances the lesions have been bilateral in the superior parts of the occipital association cortices.

Balint Syndrome (See also Chap. 13.) In this not uncommon syndrome, the illusion of a coherent and detailed visual world is disrupted and the patient perceives only disconnected individual parts of the scene. It consists of (1) a disorder of visual attention mainly to the periphery of the visual field, in which the totality of a scene is not perceived despite preservation of vision for individual elements, attention to other sensory stimuli being well preserved; (2) difficulty in grasping or touching an object under visual guidance, as though hand and eye were not coordinated (inappropriately called “optic ataxia”); and (3) an inability to project gaze voluntarily into the peripheral field and to scan it despite the fact that eye movements are full (psychic paralysis of fixation of gaze, incorrectly called “optic apraxia,” since visual scanning is not a learned task). Balint, a Hungarian neurologist, was the first to recognize this constellation. The defect is noted when the patient describes a complex scene in a disjointed way, single objects being pointed out, others missed entirely, the relationships and context of parts of the picture remaining unappreciated.

The psychic paralysis of gaze is apparent when the patient is unable to turn his eyes to fixate an object in the right or left visual field or to consistently follow a moving object. The pattern in which the patient scans a picture is haphazard and fails to encompass on entire areas. (Normal individuals accomplish visual scanning in a fairly uniform manner.) So-called optic ataxia is detected when the patient reaches for an object, either spontaneously or in response to verbal command. To reach the object, the patient engages in a tactile search with the palm and fingers, presumably using somatosensory cues to compensate for a lack of visual information. This disorder may involve one or both hands. This may give the erroneous impression that the patient is blind. In contrast, movements that do not require visual guidance, such as those directed to the body or movements of the body itself, are performed naturally. The presence of visual inattention is tested by asking the patient to carry
out tasks such as looking at a series of objects or connecting a series of dots by lines; often only one of a series of objects can be found, even though the visual fields seem to be full.

One essential feature of the Balint syndrome appears to be a failure to properly direct oculomotor function in the exploration of space. Thus it is closely related to simultanagnosia and to a special visual disorder of spatial summation (a type of amorphosynthesis). In almost all reported cases of the Balint syndrome, the lesions have been bilateral, often in the vascular border zones (areas 19 and 7) of the parieto-occipital regions, although rare instances of optic ataxia alone have been described within a single visual field contralateral to a right or left parieto-occipital lesion. The neuropsychologic aspects of the syndrome and several interesting historical notes, including the attribution of original reporting to Inouye, can be found in the comprehensive review by Rizzo and Vecera.

**Prosopagnosia** This term (from the Greek prosopon, “face,” and gnosis, “knowledge”) was introduced by Bodamer for a type of visual deficit in which the patient cannot identify a familiar face by looking at either the person or a picture, even though he knows that a face is a face and can point out its features. Such patients also cannot learn to recognize new faces. They may also be unable to interpret the meaning of facial expressions or to judge the ages or distinguish the genders of faces. In identifying persons, the patient depends on other data, such as the presence and type of glasses or moustache, the type of gait, or sound of the voice. Similarly, species of animals and birds and specific models or types of cars cannot be distinguished from one another, but the patient can still recognize an animal, bird, or car as such. Other agnosias may be present in such cases (color agnosia, simultanagnosia), and there may be topographic disorientation, disturbances of body schema, and constructional or dressing apraxia. Visual field defects are nearly always present. Some neurologists have interpreted this condition as a simultanagnosia involving facial features. Another interpretation is that the face, though satisfactorily perceived, cannot be matched to a memory store of faces. Levine has found a deficit in perception, characterized by insufficient feature analysis of visual stimuli. The small number of cases that have been studied anatomically and by computed tomography scanning and MRI indicate that prosopagnosia is most often associated with bilateral lesions of the ventromesial occipitotemporal regions (Damasio et al), but there may be exceptions that are attributable to unilateral damage.

A variant of this disorder is characterized by a specific difficulty with facial matching or discrimination from partial cues, such as portions of the face or a profile. The distinction between this deficit and the usual type of prosopagnosia rests on the use of tests that do not require memory of a specific face. This difficulty with facial matching and discrimination is more likely to be seen with lesions of the right than of the left posterior hemisphere.

Closely allied and often associated with prosopagnosia is a subtle syndrome of loss of environmental familiarity, in which the patient is unable to recognize familiar places. The patient may be able to describe a familiar environment from memory and locate it on a map, but he experiences no sense of familiarity and gets lost when faced with the actual landscape. In essence, this is an environmental agnosia. This syndrome is associated with right-sided, medial tempo-occipital lesions, although in some patients, as in those with prosopagnosia, the lesions are bilateral (Landis et al).

To be distinguished from environmental agnosia is the visual disorientation and disorder of spatial (topographic) localization, already discussed under “Parietal Lobes” (page 403). Patients with the latter disorder, in distinction to those with environmental agnosia, are unable to orient themselves in an abstract spatial setting (topographagnosia, or loss of topographic memory). Such patients cannot draw the floor plan of their house or a map of their town or the United States and cannot describe a familiar route, as from their home to their place of work, or find their way in familiar surroundings. This disorder is of interest insofar as it suggests that there are two separate processes for spatial orientation—one for the actual space, i.e., environmental (temporo-occipital), and one for the abstract topography of space (parietal).

**Visual Agnosia for Words (Alexia without Agraphia)** See Chap. 23 and further on in this chapter in the discussion of alexia without agraphia, under the “Disconnection Syndromes.”

**Color Agnosia** Here one must distinguish several different aspects of identification of colors, such as the correct perception of color (the loss of which is called color-blindness) or the naming of a color. The common form of retinal color-blindness is congenital and is readily tested by the use of Ishihara plates. Acquired color-blindness due to a cerebral lesion, with retention of form vision, is referred to as central achromatopsia. Here the disturbance is one of hue discrimination; the patient cannot sort a series of colored wools according to hue (Holmgren test) and may complain that colors have lost their brightness or that everything looks gray.

Achromatopsia is frequently associated with visual field defects and with prosopagnosia. Most often the field defects are bilateral and tend to affect the upper quadrants. However, full-field achromatopsia may exist with retention of visual acuity and form vision. There may also be a hemi- or quadrant-achromatopsia without other abnormalities, although special testing is required to reveal this defect. These features, together with the usually associated prosopagnosia, point to involvement of the inferomesial occipital and temporal lobe(s) and the lower part of the striate cortex or optic radiation (Meadows; Damasio et al). The existence of a central achromatopsia is not surprising in view of the animal studies of Hubel, which identified sets of cells in areas 17 and 18 that are activated only by color stimuli.

A second group of patients with color agnosia have no difficulty with color perception (i.e., they can match seen colors), but they cannot reliably name them or point out colors in response to their names. They have a color anoma, of which there are at least two varieties. One is typically associated with pure word-blindness, i.e., alexia without agraphia, and is best explained by a disconnection of the primary visual areas from the language areas (see further on). In the second variety, the patient fails not only in tasks that require the matching of a seen color with its spoken name but also in purely verbal tasks pertaining to color naming, such as naming the colors of common objects (e.g., grass, banana). This latter disorder is probably best regarded as a form of anomia, in which the aphasia is more or less restricted to the naming of colors (Meadows). According to Damasio and associates, the lesion has involved the mesial part of the left hemisphere at the junction of the occipital and temporal lobes, just below the splenium of the corpus callosum. All their patients also had a right homonymous hemianopia as a result of destruction of the left lateral geniculate body, optic radiation, or calcarine cortex.

The Theoretical Problem of Visual and Other Agnosias From the foregoing discussion, it is apparent that the term visual agnosia applies to a series of visual perceptive disorders that include, in varying combinations, faults of discrimination, identification, and
recognition of faces, objects, pictures, colors, spatial arrangements, and words. The diagnosis of these states is predicated on the assumption that the failure in perception occurs in spite of intact visual acuity and adequate language and mental function. When examined carefully, agnostic patients usually do not satisfy all these criteria and instead have a number of other derangements that may at least in part explain their perceptual incompetence. Often there is a unisensory or poly sensory disturbance, an inadequacy of memory or of naming, or an impairment of visual oculomotor or visuomanual control. Anatomic studies have established that disturbances of recognition of complex forms, human faces, and spatial arrangements accompany right (nondominant) parieto-occipital lesions more often than left-sided ones. Disturbances of perception of graphic symbols of objects, of color discrimination, and naming—in short, all of the lexical aspects of recognition—are virtually always associated with left parieto-occipital lesions. Variations in the clinical effects of such lesions are dependent not only on their location and size but also on the particular tests used to elicit these effects and whether they involve learning, recognition, and recall.

But there have been many critics of the concept of agnosia as a higher-order perceptual disturbance that can be clearly separated from loss of elementary sensation. Such a division is said to perpetuate an archaic view of sensory reception in the brain as consisting of two separable functional attributes: elementary sensation and perception. Bay, for example, claimed that careful testing of patients with visual agnosia always brings to light some degree of diminished vision in combination with general defects such as confusion and mental deterioration. Others (Geschwind; Sperry and colleagues) have emphasized that the visual agnosias depend on disconnections of the visual receptive zones of the brain from the language areas of the left hemisphere, the learning and memory zones of the temporal lobes, the suprasensory zones of the parietal lobes, and the motor regions. Hécaen, Gassel, and McCarthy and Warrington have presented the evidence for and against these points of view, the first of which argues for a diminution of sensory function and the second, for a genuine disconnection.

The reported cases of visual agnosia emphasize the complexity of the perceptive process and the inadequacy of our knowledge of the physiology of the several receptive zones of the occipital lobes. The fact that in some cases there are impairments of primary sensation that can be elicited by careful testing of visual function—using tachistoscopic stimuli, visual adaptation, perception of pattern, flicker-fusion, etc.—cannot be disputed. However, even when present, such abnormalities would not fully explain the loss of discrimination and the inability to visualize or imagine the form and color of objects, their spatial arrangements, and their names. Failure of a sensation to activate these visual memories must involve a higher-order disturbance of cerebral function in the heteromodal association areas. Here sensory and motor functions are always integrated, the latter being essential for proper scanning and exploring by the sense organs. And to reduce the agnosias to a series of disconnections between the striate and para striate cortex and other parts of the brain, although an interesting approach, leads to an overly simplified mechanistic view of cerebral activity, which probably will not be sustained as more knowledge of cerebral physiology is acquired. There is still a great need for the study of cases in which sensation and perception have been tested in detail and the anatomy of the lesion, in its stable end stage, has been carefully determined.

The effects of disease of the occipital lobes may be summarized as follows:

I. Effects of unilateral disease, either right or left
   A. Contralateral (congruent) homonymous hemianopia, which may be central (splitting the macula) or peripheral; also homonymous hemiachromatopsia
   B. Elementary (unformed) hallucinations—usually due to irritative lesions

II. Effects of left occipital disease
   A. Right homonymous hemianopia
   B. If deep white matter or splenium of corpus callosum is involved, alexia and color-naming defect
   C. Visual object agnosia

III. Effects of right occipital disease
   A. Left homonymous hemianopia
   B. With more extensive lesions, visual illusions (metamorphopsias) and hallucinations (more frequent with right-sided than left-sided lesions)
   C. Loss of topographic memory and visual orientation

IV. Bilateral occipital disease
   A. Cortical blindness (pupils reactive)
   B. Anton syndrome (visual anosognosia, denial of cortical blindness)
   C. Loss of perception of color (achromatopsia)
   D. Prospagnosia (temporo-occipital), simultanagnosia (parieto-occipital)
   E. Balint syndrome (parieto-occipital)

**Disturbances of the Nondominant Cerebral Hemisphere**

A line of disagreement, as old as neurology itself, pertains to the relationship between the two cerebral hemispheres. Fechner, in 1860, speculated that since the two hemispheres, joined by the corpus callosum, were virtual mirror images of one another and functioned in totality in conscious life, separating them would result in two minds. William McDougall rejected this idea and is said to have offered to have his own brain divided by Charles Sherrington should he have an incurable disease. He died of cancer, but the callosotomy was considered unnecessary, for already there were indications from the work of Sperry and colleagues that when separated, the two hemispheres had different functions, as indicated in the next section, “Disconnection Syndromes.”

The practice of surgical sectioning of the corpus callosum for the control of epilepsy had greatly stimulated interest in the functions of the right cerebral hemisphere when isolated from the left. It is in the sphere of visuospatial perception that right hemispheric dominance is most convincing. Lesions of the right posterior cerebral region result in an inability to utilize information about spatial relationships in making perceptual judgments and in responding to objects in a spatial framework. This is manifest in constructing figures (constructional apraxia), in the spatial orientation of the patient in relation to the environment (topographic agnosia), in identifying faces (prosopagnosia), and in relating a scattering of visual stimuli to one another (simultanagnosia). Also, there are claims that the right hemisphere is more important than the left in visual imagery, attention, emotion (both in feeling and in the perception of emotion in others), and manual drawing (but not writing); in respect to these functions, however, the evidence
is less firm. The idea that attention is a function of the right hemisphere derives from the neglect of left visual space and of somatic sensation in the anosognosic syndrome and also from the apathy that characterizes such patients. Certainly the popular notion of the right hemisphere as "emotional" in contrast to the left one as "logical" has no basis in fact and represents a gross oversimplification of brain function and localization.

Similar issues arise, of course, in relation to handedness and language dominance in the left hemisphere as discussed in the following chapter. Here we only comment on how intriguing it is that praxis and linguistic skill are aligned on the same side of the brain, suggesting that an essential property of the dominant hemisphere is its ability to comprehend and manipulate symbolic representations of all types.

**Disconnection Syndromes**

Following the insightful clinical observations and anatomic studies of Wernicke, Dejerine, and Liepmann, the concept of disconnection of parts of one or both cerebral hemispheres as a cause of neurologic difficulty was introduced to neurologic thinking. In more recent years, these ideas were resurrected and modernized by Geschwind and greatly extended by Sperry and by Gazzaniga. Geschwind called attention to several clinical syndromes resulting from interruption of the connections between the two cerebral hemispheres in the corpus callosum or between different parts of one hemisphere. Some of these are illustrated in Fig. 22-6.

When the entire corpus callosum is destroyed by tumor or surgical section, the language and perception areas of the left hemisphere are isolated from the right hemisphere. Patients with such lesions, if blindfolded, are unable to match an object held in one hand with that in the other. Objects placed in the right hand are named correctly, but not those in the left. Furthermore, if rapid presentation is used to avoid bilateral visual scanning, such patients cannot match an object seen in the right half of the visual field with one in the left half. They are also alexic in the left visual field, since the verbal symbols that are seen there and are projected to regions of the right hemisphere have no access to the language areas of the left hemisphere. If given a verbal command, such patients will execute it correctly with the right hand but not with the left; if asked to write from dictation with the left hand, they will produce only an illegible scrawl. Many remarkable conclusions regarding the nature of behavior and the special roles of each cerebral hemisphere have been drawn from clever observations of patients with callosal section. Extensive discussion of these neuropsychologic abnormalities cannot be undertaken here; suffice it to say that these are not features seen in patients with the usual neurologic diseases, but they are nonetheless of interest to neurologists and are discussed in the writings of Gazzaniga.

In most lesions confined to the posterior portion of the corpus callosum (splenium), only the visual part of the disconnection syndrome occurs. Cases of occlusion of the left posterior cerebral artery provide the best examples. Since infarction of the left occipital lobe causes a right homonymous hemianopia, all visual information needed for activating the speech areas of the left hemisphere must thereafter come from the right occipital lobe. The patient with a lesion of the splenium of the corpus callosum or the adjacent white matter cannot read or name colors because the visual information cannot reach the left language areas. There is, however, no difficulty in copying words; presumably the visual information for activating the left motor area crosses the corpus callosum more anteriorly. Spontaneous writing and writing to dictation are also intact because the language areas, including the angular gyrus, Wernicke’s and Broca’s areas, and the left motor cortex, are intact and interconnected, but after a delay, the patient is unable to read what he has previously written (unless it was memorized). This is the syndrome of alexia without agraphia mentioned earlier and discussed further on page 422.

A lesion that is limited to the anterior third of the corpus callosum (or a surgical section of this part, as in patients with intractable epilepsy) surprisingly does not result in an apraxia of the left hand. A section of the entire corpus callosum does result in such an apraxia, i.e., a failure of only the left hand to obey spoken commands, the right one performing normally, indicating that the fiber systems that connect the left to the right motor areas cross in the corpus callosum posterior to the genu (but anterior to the splenium). Object naming and matching of colors without naming them are also done without error. However, blinded, the patient cannot name a finger touched on the left hand or use it to touch a designated part of the body.

Of interest to the authors is the fact that one sometimes encounters patients with a lesion in all or some part of the corpus callosum without being able to demonstrate any aspect of the aforementioned disconnection syndromes. Is the lesion incomplete? Probably not in every case. Notable is the observation that in some patients with a congenital agenesis of the corpus callosum (a not uncommon developmental abnormality), none of the interhemispheric disconnection syndromes can be found. One can only suppose that in such patients information is transferred by another route—perhaps the anterior or posterior commissure—or that dual dominance for language and praxis was established during early development. (See a review of this subject by Lassonde and Jeeves.)

In addition to alexia without agraphia, the following intrahemispheric disconnections have received the most attention. They are mentioned here only briefly and are considered in more detail in the following chapter.

1. **Conduction (also called “central”) aphasia.** The patient has severely impaired repetition, but fluent and paraphasic speech and writing and relatively intact comprehension of spoken and written language. Wernicke’s area in the temporal lobe is putatively separated from Broca’s area, presumably by a lesion in the arcuate fasciculus or external capsule or subcortical white matter. However, most often the lesion is in the supramarginal gyrus, as discussed in Chap. 23.

2. **Ideomotor (“sympathetic”) apraxia in Broca’s aphasia.** By destroying the origin of the fibers that connect the left and right motor association cortices, a lesion in the more anterior parts of the corpus callosum or the subcortical white matter underlying Broca’s area and contiguous frontal cortex causes an apraxia of commanded movements of the left hand (see Chap. 3 and earlier discussion).

3. **Pure word-deafness.** Although the patient is able to hear and identify nonverbal sounds, there is loss of ability to discriminate speech sounds, i.e., to comprehend spoken language. The patient’s speech may be paraphasic, presumably because of the inability to monitor his own speech. This defect has been attributed to a subcortical lesion of the left temporal lobe, spanning Wernicke’s area and interrupting also those
auditory fibers that cross in the corpus callosum from the opposite side. Thus there is a failure to activate the left auditory language area (Wernicke’s area). Bilateral lesions of the auditory cortex have the same effect (see Chap. 23).

**Special Neuropsychologic Tests**

In the study of focal cerebral disease, there are two complimentary approaches—the clinical-neurologic and the neuropsychologic. The first consists of the observation and recording of qualitative changes in behavior and performance and the identification of syndromes from which one may deduce the locus and nature of certain diseases. The second consists of recording a patient’s performance on a variety of psychologic tests that have been standardized in a large population of age-matched normal individuals. These tests provide data that can be graded and treated statistically. An example is the deterioration index, deduced from the difference in performance on subtest items of the Wechsler Adult Intelligence Scale that hold up well in cerebral diseases (vocabulary, information, picture completion, and object assembly) and those that undergo impairment (digit span, similarities, digit symbol, and block design). A criticism of this index and others is the implicit assumption that cerebrocortical activity is a unitary function. However, it cannot be denied that certain psychometric scales reveal disease in certain parts of the cerebrum more than in others. These tests allow comparison of the patient’s deficits from one point in the course of an illness to another. Walsh has listed the ones that he finds most valuable. In addition to the Wechsler Adult Intelligence Scale, Wechsler Memory Scale, and an aphasia screening test, he recommends the following for quantifying particular psychologic abilities and skills:

I. **Frontal lobe disorders**
   
   A. Milan Sorting Test, Halstead Category Test, and Wisconsin Card-Sorting Test as tests of ability to abstract and shift paradigms
   
   B. The Porteus Maze Test, Reitan Trail-Making Test, and the recognition of figures in the Figure of Rey as tests of planning, regulating, and checking programs of action
   
   C. Benton’s Verbal Fluency Test for estimating verbal skill and verbal regulation of behavior

II. **Temporal lobe disorders**

   A. Figure of Rey, Benton Visual Retention Test, Illinois Nonverbal Sequential Memory Test, Recurring Non-sense Figures of Kimura, and Facial Recognition Test as modality-specific memory tests
   
   B. Milner’s Maze Learning Task and Lhermitte-Signoret amnesic syndrome tests for general retentive memory
   
   C. Seashore Rhythm Test, Speech-Sound Perception Test from the Halstead-Reitan battery, Environmental Sounds Test, and Austin Meaningless Sounds Test as measures of auditory perception

III. **Parietal lobe disorders**

   A. Figure of Rey, Wechsler Block Design and Object Assembly, Benton Figure Copying Test, Halstead-Reitan Tactual Performance Test, and Fairfield Block Substitution Test as tests of constructional praxis
   
   B. Several mathematical and logigrammatical tests as tests of spatial synthesis
   
   C. Cross-modal association tests as tests of suprasensory integration
   
   D. Benson-Barton Stick Test, Cattell’s Pool Reflection Test, and Money’s Road Map Test, as tests of spatial perception and memory

IV. **Occipital lobe disorders**

   A. Color naming, color form association, and visual irremissence, as tests of visual perception; recognition of faces of prominent people, map drawing

It is the authors’ opinion that the data obtained from the above tests should be used to supplement clinical observations. Taken alone, they cannot be depended upon for the localization of cerebral lesions.

CHAPTER 23
DISORDERS OF SPEECH AND LANGUAGE

Speech and language functions are of fundamental human significance, both in social interaction and in private intellectual life. When they are disturbed as a consequence of brain disease, the resultant functional loss exceeds in many ways all others in gravity—even blindness, deafness, and paralysis.

The neurologist is concerned with all derangements of speech and language, including those of reading and writing, because they and are almost invariably manifestations of disease of the brain. Broadly viewed, language is the mirror of all higher mental activity. In a narrower context, language is the means whereby patients communicate their complaints and problems to the physician and at the same time the medium for all delicate interpersonal transactions. Therefore any disease process that interferes with speech or the understanding of spoken words touches the very core of the physician-patient relationship. Finally, the study of language disorders serves to illuminate the abstruse relationship between psychologic functions and the anatomy and physiology of the brain. Language mechanisms fall somewhere between the well-localized sensorimotor functions and the more widely distributed complex mental operations such as imagination and thinking, which cannot be localized.

General Considerations

It has been remarked that as human beings, we owe our commanding position in the animal world to two faculties: (1) the ability to develop and employ verbal symbols as a background for our own ideation and as a means of transmitting thoughts, by spoken and written word, to others of our kind and (2) the remarkable facility in the use of our hands. One curious and provocative fact is that both language and manual dexterity (as well as praxis) have evolved in relation to particular aggregates of neurons and pathways in one (the dominant) cerebral hemisphere. This is a departure from most other localized neurophysiologic activities, which are organized according to a contralateral or bilateral and symmetrical plan. The dominance of one hemisphere, usually the left, emerges together with speech and the preference for the right hand, especially for writing. It follows that a lack of development or loss of cerebral dominance as a result of disease deranges both these traits, causing aphasia and apraxia.

There is abundant evidence that higher animals are able to communicate with one another by vocalization and gesture. However, the content of their communication is their feeling or reaction of the moment. This emotional language, as it is called, was studied by Charles Darwin, who noted that it undergoes increasing differentiation in the animal kingdom. Only in the chimpanzee do the first semblances of propositional language become recognizable. Indeed, there are distinct differences between the human and chimp versions of a gene called FOXP2, which has been linked to the ability to produce language (See Balter). Instinctive patterns of emotional expression are observed in human beings. They are the earliest modes of expression to appear (in infancy) and may have been the original forms of speech in primitive human beings. Moreover, the utterances we use to express joy, anger, and fear are retained even after destruction of all the language areas in the dominant cerebral hemisphere. The neural arrangement for this paralinguistic form of communication (intonation, exclamations, facial expressions, eye movements, body gestures), which subserves emotional expression, is bilateral and symmetrical and does not depend solely on the cerebrum. The experiments of Cannon and Bard demonstrated that emotional expression is possible in animals even after removal of both cerebral hemispheres provided that the diencephalon, particularly its hypothalamic part, remains intact. In the human infant, emotional expression is well developed at a time when much of the cerebrum is still immature.

Propositional, or symbolic, language differs from emotional language in several ways. Instead of communicating feelings, it is the means of transferring ideas from one person to another, and it requires the substitution of a series of sounds or marks for objects, persons, and concepts. This is the essence of language. It is not instinctive but learned and is therefore subject to all the modifying social and cultural influences of the environment. However, the learning process becomes possible only after the nervous system has attained a certain degree of maturation. Facility in symbolic language, which is acquired over a period of 15 to 20 years, depends then on maturation of the nervous system and on education.

Although speech and language are closely interwoven functions, they are not synonymous. A derangement of language function is always a reflection of an abnormality of the brain and, more specifically, of the dominant cerebral hemisphere. A disorder of speech may have a similar origin, but not necessarily; it may be due to abnormalities in different parts of the brain or to extracerebral mechanisms. Language function involves the comprehension, formulation, and transmission of ideas and feelings by the use of conventionalized verbal symbols, sounds, and gestures and their sequential ordering according to accepted rules of grammar. Speech, on the other hand, refers more to the articulatory and phonetic aspects of verbal expression.

The profound importance of language may not be fully appreciated unless one reflects on the proportion of our time devoted to purely verbal pursuits. External speech, or orphaphy, by which is meant the expression of thought by spoken or written words and the comprehension of the spoken or written words of others, is an almost continuous activity when human beings gather together; inner speech, or endophasy, i.e., the silent processes of thought and the formulation in our minds of unuttered words on which thought depends, is “the coin of mental commerce.” The latter is almost incessant during our preoccupations, since we think always with words. Thought and language are thus inseparable. In learning to think, the child talks aloud to himself and only later learns to suppress the vocalization. Even adults may mutter subconsciously when pondering a difficult proposition. As Gardiner remarks, any abstract thought can be held in mind only by the word or mathematical symbol denoting it. It is virtually impossible to comprehend what is meant by the word religion, for example, without the controlling and limiting consciousness of the word itself. “Words have
thus become an integral part of the mechanism of our thinking and remain for ourselves and for others the guardians of our thoughts” (quoted from Brain). This is the reasoning that persuaded Head, Wilson, Goldstein, and others that any comprehensive theory of language must include explanations in terms not only of cerebral anatomy and physiology but also of the psycholinguistic processes that are involved.

**Anatomy of the Language Functions**

The conventional teaching, based on correlations between various disorders of language and damage to particular areas of the brain, postulates four main language areas, situated, in most persons, in the left cerebral hemisphere (Fig. 23-1). The entire language zone that encompasses these areas is perisylvian, i.e., it borders the sylvian fissure. Two language areas are receptive and two are executive, i.e., the latter are concerned with the production (output) of language. The two receptive areas are closely related and embrace what has been referred to as the central language zone. The main receptive area, subserving the perception of spoken and probably of internal language, occupies the posterior-posterosuperior temporal area (the posterior portion of area 22) and Heschl’s gyri (areas 41 and 42). The posterior part of area 22 in the planum temporale is referred to as Wernicke’s area. A second receptive area, subserving the perception of written language, occupies the angular gyrus (area 39) in the inferior parietal lobule, anterior to the visual receptive areas. The supramarginal gyrus, which lies between these auditory and visual language “centers,” and the inferior temporal region, just anterior to the visual association cortex, are probably part of this central language zone as well. Here are located the integrative centers for cross-modal visual and auditory language functions.

The main executive, or output, region, situated at the posterior end of the inferior frontal convolution (Brodmann’s areas 44 and 45), is referred to as Broca’s area and is concerned with motor aspects of speech. In some models, visually perceived words are thus afferent and efferent localization as discussed above, but
given expression in writing through a fourth language area, the so-called Exner writing area in the posterior part of the second frontal convolution, a concept that is still controversial in view of the fact that widely separated parts of the language zone may cause a disproportionate disorder of writing. In any case, there are two parallel systems for understanding the spoken word and producing speech and for the understanding of the written word and producing writing. They develop separately but are the integral components of the semantic system.

These sensory and motor areas are intricately connected with one another by a rich network of nerve fibers, one large bundle of which, the arcuate fasciculus, passes through the isthmus of the temporal lobe and around the posterior end of the sylvian fissure; other connections may traverse the external capsule of the lenticular nucleus (subcortical white matter of the insula). Many additional corticocortical connections and other fiber systems lead into the perisylvian zones and project from them to other parts of the brain. Furthermore, the visual receptive and somatosensory zones are integrated in the parietal lobe, and the auditory receptive zones in the temporal lobe. Of special importance for the production of speech are the short association fibers that join Broca’s area with the lower rolandic cortex, which, in turn, innervates the muscles of the lips, tongue, pharynx, and larynx. The putative Exner writing area is also integrated with the motor apparatus for the muscles of the hand. The perisylvian language areas are also connected with the striatum and thalamus and with corresponding areas in the minor (nondominant) cerebral hemisphere through the corpus callosum and anterior commissure (see Fig. 22-6).

There has been considerable difference of opinion concerning the status of cortical language areas, and objection has been made to calling them “centers,” for they do not represent histologically circumscribed structures of constant function. Moreover, a competent neuroanatomist would not be able to distinguish the cortical language areas microscopically from the cerebral cortex that surrounds them. Some of the perceptive areas are polymodal, i.e., they are activated by auditory, visual, and tactile stimuli. Presumably, their function is integrative. The lack of comparability with the motor and sensory regions of the cortex is demonstrated by observations during the electrical stimulation of the anterior cortical language areas while the patient is alert and talking (during craniotomy under local anesthesia); stimulation may induce a simple vocalization, usually a single-vowel monotone, but otherwise causes only an arrest of speech. Similarly, electrical stimulation of Wernicke’s area causes errors of speech, such as stumbling over a word or saying the wrong word.

As indicated earlier, knowledge of the anatomy of language has come almost exclusively from the postmortem study of humans with focal brain diseases. Two major theories emerged from these studies. One has subdivided the language zone into separate afferent (auditory and visual) receptive parts, connected by identifiable tracts to the executive (effector-expressive) centers. Depending on the exact anatomy of the lesions, a number of special syndromes are elicited. The other theory, advanced originally by Marie (he later claims to have changed his mind) and supported by Head, Wilson, Brain, and Goldstein, favored the idea of a single language mechanism, roughly localized in the opercular, or perisylvian, region of the dominant cerebral hemisphere. The aphasia in any particular case was presumably due to the summation of damage to input or output modalities relative to this central language zone. Undeniably, there is, within the perisylvian language area, recognizable afferent and efferent localization as discussed above, but
there is also an undifferentiated central integrative mass action, in which the degree of deficit is to a considerable extent influenced by the size of the lesion. Thus a strict division of aphasias into executive and receptive, while still a strong practical concept, is not fully borne out by clinical observation. Nevertheless, there are several localizable language functions in the perisylvian cortex.

Carl Wernicke, of Breslau, Germany, more than any other person, must be credited with the anatomic-physiologic and psychological scheme upon which many contemporary ideas of aphasia rest. Earlier, Paul Broca (1865), and, even before him, Dax (1836), had made the fundamental observations that a lesion of the insula and the overlying operculum deprived a person of speech and that such lesions were always in the left hemisphere. Wernicke’s thesis was that there were two major anatomic loci for language: (1) an anterior locus, in the posterior part of the inferior frontal lobe (Broca’s area), in which were contained the “memory images” of speech movements, and (2) the insular region and adjoining parts of the posterior perisylvian cortex, in which were contained the images of sounds. (Meynert had already shown that aphasia could occur with lesions in the temporal lobe, Broca’s area being intact). Wernicke believed that the fibers between these regions ran in the insula and mediated the psychic reflex arc between the heard and spoken word. Later, Wernicke came to accept von Monakow’s view that the connecting fibers ran around the posterior end of the sylvian fissure, in the arcuate fasciculus.

Wernicke gave a comprehensive description of the receptive or sensory aphasia that now bears his name. The four main features, he pointed out, were (1) a disturbance of comprehension of spoken language and (2) of written language (alexia), (3) aphagricia, and (4) fluent paraphasic speech. In Broca’s aphasia, by contrast, comprehension was intact, but the patient was mute or employed only a few simple words. Wernicke also theorized that a lesion interrupting the connecting fibers between the two cortical speech areas would leave the patient’s comprehension undisturbed but would prevent the intact sound images from exerting an influence on the choice of words. Wernicke proposed that this variety of aphasia be called Leitungsaphasie, or conduction aphasia (called central aphasia by Kurt Goldstein and deep aphasia by Martin and Saf-fran).

Careful case analyses since the time of Broca and Wernicke have repeatedly borne out these associations between a receptive (Wernicke) type of aphasia and lesions in the posterior perisylvian region and between a predominantly (Broca) motor aphasia and lesions in the posterior part of the inferior frontal lobe and the adjacent, insular, and opercular regions of the frontal cortex. The concept of a conduction aphasia, based on an interruption of pathways between Wernicke’s and Broca’s zones, has been the most difficult to accept, because it presupposes a neat separation of sensory and motor functions, which is not in line with contemporary views of sensorimotor physiology of the rest of the nervous system or with the recent analyses of language by cognitive neuropsychologists (Margolin). Nevertheless, there are in the medical literature a number of descriptions and we have certainly encountered cases that conform to the Wernicke model of conduction aphasia; the lesion in these cases may lie in the parietal operculum, involving the white matter deep to the supramarginal gyrus, where it presumably interrupts the arcuate fasciculus and posterior insular subcortex (this issue is discussed further on).

How these regions of the brain are organized into separable but interactive modules and how they can be activated and controlled by a variety of visual and auditory stimuli and frontal mo-tivational mechanisms, resulting in the complex behavior of which we make casual daily use in interpersonal communication, is just beginning to be studied by linguists and cognitive neuropsychologists. They, for example, are dissecting language into its most basic elements—phonemes (the smallest units of sound recognizable as language), morphemes (the smallest meaningful units of a word), graphemes, lexical and semantic elements (words and their meanings), and syntax (sentence structure). In general, as a restatement of the Wernicke-Broca scheme, phonologic difficulties correlate with left frontal lesions; semantic-comprehension difficulties, with left temporal lesions; and alexia and agraphia, with inferior parietal lesions. These elements, or modules, have been diagramed by psycholinguists as a series of boxes and are connected to one another by arrows to indicate the flow of information and the manner in which it influences the spoken output of language. These “boxologies,” as they are called, are not inconsistent with current psychologic theory, which views language functions as the result of synchronized activity in vast neuronal networks made up of many cerebrocortical regions and their interconnecting pathways (Damasio and Damasio, 1989). On the other hand, despite this level of theoretical sophistication, attempts to delineate the anatomy of speech and language disorders by means of brain imaging techniques in aphasic patients have been disappointing. Using computed tomography (CT), Roch-LeCours and Lhermitte were unable to establish a consistent correspondence between the type of aphasia and the demonstrable lesion. Also, Willmes and Poeck, in a retrospective study of 221 aphasic patients, failed to demonstrate an unequivocal association between the type of aphasia and the CT localization of the lesion. This poor correlation may in part be related to the timing and the crudity of the CT scan. MRI scans performed soon after a stroke show somewhat more consistent correlations between the type of language disturbance and the location of lesions in the perisylvian cortex.

Functional magnetic resonance imaging (fMRI) while subjects are engaged in language production and comprehension may prove to be superior to anatomic correlations of brain lesions for understanding the language process, but so far only the broadest rules of localization can be confirmed. Up to now, studies of blood flow and topographic physiology during the acts of reading and speaking, while generally affirming nineteenth-century models of language (see Price), have shown widespread activation of Wernicke’s and Broca’s areas as well as of the supplementary motor area and areas of the opposite hemisphere.

Although localization of the lesion that produces aphasia is in most instances roughly predictable from the clinical deficit, there are wide variations. The inconsistency has several explanations, the most popular being that the net effect of any lesion depends not only on its locus and extent but also on the degree of cerebral dominance—i.e., on the degree to which the minor hemisphere assumes language function after damage to the major one. According to this view, a left-sided lesion has less effect on language function if cerebral dominance is poorly established than if dominance is strong. In likelihood there are variations among individuals in the distribution of the language areas in the left perisylvian area. Another explanation invokes the poorly understood concept that individuals differ in the ways in which they acquire language as children. This is believed to play a role in making available alternative means for accomplishing language tasks when the method initially learned has been impaired through brain disease. The extent to which improvement of aphasia represents “recovery”
of function or generation of new modes of response has not been settled to the present day.

**Cerebral Dominance and its Relation to Language and Handedness**

The functional supremacy of one cerebral hemisphere is fundamental to language function. There are many ways of determining that the left side of the brain is dominant: (1) by the loss of speech that occurs with disease in certain parts of the left hemisphere and its preservation with lesions involving corresponding parts of the right hemisphere; (2) by preference for and greater facility in the use of the right hand, foot, and eye; (3) by the arrest of speech with a focal seizure or with electrical or magnetic stimulation of the anterior language area; (4) by the injection of sodium amytal into the left internal carotid artery (the Wada test—a procedure that produces mutism for a minute or two, followed by misnaming, including perseveration and substitution; misreading; and paraphasic speech—lasting 8 to 9 min in all); (5) by dichotic listening, in which different words or phonemes are presented simultaneously to the two ears (yielding a right ear—left hemisphere advantage); (6) by observing increases in cerebral blood flow during language processing; and (7) by lateralization of speech and language functions following commissurotomy.

Approximately 90 to 95 percent of the general population is right-handed; i.e., they innately choose the right hand for intricate, complex acts and are more skillful with it. The preference is more complete in some persons than in others. Most individuals are neither completely right-handed nor completely left-handed but strongly favor one hand for more complicated tasks.

The reason for hand preference is not fully understood. There is strong evidence of a hereditary factor, but the mode of inheritance is uncertain. Yakovlev and Rakic, in a study of infant brains, observed that the corticospinal tract coming from the left cerebral hemisphere contains more fibers and decussates higher than the tract from the right hemisphere. Learning is also a factor; many children are shifted at an early age from left to right (shifted sinistrals) because it is a perceived handicap to be left-handed in a right-handed world. Most right-handed persons, when obliged to use only one eye (looking through a keyhole, gunstock, telescope, etc.), sight with the right eye, and it has been said that eye preference coincides with hand preference. Even if true, this still does not account for eye dominance. It is noteworthy that handedness develops simultaneously with language; the most that can be said at present is that localization of language and preference for one eye, hand, and foot as well as praxis of the right hand are all manifestations of some fundamental, partly inherited tendency not yet defined.

There are slight but definite anatomic differences between the dominant and the nondominant cerebral hemispheres. The *planum temporale*, the region on the superior surface of the temporal lobe posterior to Heschl’s gyri and extending to the posterior end of the sylvian fissure, has been found to be slightly larger on the left in 65 percent of brains and larger on the right in only 11 percent (Geschwind and Levitsky). LeMay and Culebras noted in cerebral angiograms that the left sylvian fissure is longer and more horizontal than the right and that there is a greater mass of cerebral tissue in the area of the left temporoparietal junction. CT scanning has shown the right occipital horn to be smaller than the left, indicative perhaps of a greater right-sided development of visuo-spatial connections. Also, subtle cytoarchitectonic asymmetries of the auditory cortex and posterior thalamus have been described; these and other biologic aspects of cerebral dominance have been reviewed by Geschwind and Galaburda and relate also to developmental dyslexia (Chap. 28).

Left-handedness may result from disease of the left cerebral hemisphere in early life; this probably accounts for its higher incidence among the mentally retarded and brain-injured. Presumably the neural mechanisms for language then come to be represented in the right cerebral hemisphere. Handedness and cerebral dominance may fail to develop in some individuals; this is particularly true in certain families. In these individuals, defects in reading—as well as stuttering, mirror writing, and general clumsiness—are much more frequent and persistent during development.

In right-handed individuals, aphasia is almost invariably related to a left cerebral lesion; aphasia in such individuals as a result of purely right cerebral lesions (“crossed aphasia”) is very rare, occurring in only 1 percent of cases (Joanette et al). Cerebral dominance in ambidextrous and left-handed persons is not nearly so uniform. In a large series of left-handed patients with aphasia, 60 percent had lesions confined to the left cerebral hemisphere (Goodglass and Quadfasel). However, in the relatively rare case of aphasia due to a right cerebral lesion, the patient is nearly always left-handed; moreover, the language disorder in some such patients is less severe and enduring than in right-handed patients with comparable lesions in the left hemisphere (Gloning, Subirana). The latter findings suggest a bilateral albeit unequal representation of language functions in non—right-handed patients. Using the Wada test, Milner and colleagues found evidence of bilateral speech representation in about 15 percent of 212 consecutively studied left-handed patients.

There are undoubtedly language capacities of the nondominant hemisphere, but they have not been documented by careful anatomic studies. As mentioned above, there is always some uncertainty as to whether residual function after lesions of the dominant hemisphere can be traced to recovery of parts of its language zones or to activity of the minor hemisphere. The observations of Levine and Mohr suggest that the nondominant hemisphere has only a limited capacity to produce oral speech after extensive damage to the dominant hemisphere; their patient recovered the ability to sing, recite, curse, and utter one- or two-word phrases, all of which were abolished by a subsequent right hemisphere infarction. The fact that varying amounts of language function may remain after dominant hemispherectomy in adults with glioma also suggests a definite though limited capacity of the minor hemisphere for language production. Kinsbourne’s observations of the effect of amyot injections into the right-hemispheral arteries of patients who are aphasic from left-sided lesions make the same point. However, congenital absence (or surgical section) of the corpus callosum, permitting the testing of each hemisphere, has shown virtually no language functions of the right hemisphere. Some of these differences are attributable to variations in the clinical state of the subjects being tested and in the methods of language testing.

Despite its minimal contribution to the purely linguistic or propositional aspects of language, the right hemisphere does have a role in the implicit communication of feelings and emotion through expressed language. It has long been known that when angered, globally aphasic patients can shout or curse. These modulatory aspects of language are subsumed under the term *prosody*, by which is meant the melody of speech—its intonation, inflection, and pauses—all of which have emotional overtones. These prosodic components of speech and the gestures that accompany them...
enhance the meaning of the spoken word and endow language with its richness and vitality. The related issue of the accent of speech, which carries such a strong regional identity, probably also has an anatomic meaning, but one that remains obscure (see later comments on the “Foreign Accent Syndrome”).

Many diseases and focal cerebral lesions mute the prosody of speech, the most dramatic examples being the hypophonic monotone of Parkinson disease and the effortful utterances of Broca’s aphasia. But in recent years, largely through the work of Ross, it has been shown that this deficit in prosody is also present in patients with strokes involving the territory of the right middle cerebral artery, i.e., in portions of the nondominant hemisphere that mirror the language areas of the left hemisphere. There is impairment both of comprehending and of producing the emotional content of language, based partly on observations in the Williams syndrome, in which mental retardation is associated with a preserved language skill that is sometimes striking in degree (Chap. 38). In this disease, the cerebellum is spared in the face of greatly diminished volume of the cerebral hemispheres (see also Leiner et al). Some studies of cerebral blood flow also implicate the cerebellum in various language functions; but based on our clinical experience, we would judge any language deficits from cerebellar disease to be subtle or nonexistent.

**DISORDERS OF SPEECH AND LANGUAGE DUE TO DISEASE**

These may be divided into four categories:

1. A loss or impairment of the production and/or comprehension of spoken or written language due to an acquired lesion of the brain. This condition is called *aphasia* or *dysphasia*.
2. Disturbances of speech and language with diseases that globally affect higher-order mental function, i.e., in confusion, delirium, mental retardation, and dementia. Speech and language functions are seldom lost in these conditions but are deranged as part of a general impairment of perceptual and intellectual functions. In Alzheimer disease, for example, a gradual impairment of all elements of language without the emergence of any of the classic aphasic syndromes constitutes an important part of the clinical picture (Chap. 21). Common to this category are certain special disorders of speech, such as extreme perseveration (*palilalia*) and *echolalia*, in which the patient repeats, parrot-like, words and phrases that he hears (see further on). The odd constructs of language and other disorders of verbal communication of schizophrenics and some autistic individuals—extending to the production of meaningless phrases, neologisms, or jargon—probably belong in this category as well.
3. A defect in articulation with intact mental functions and comprehension of spoken and written language and normal syntax (grammatical construction of sentences). This is a pure motor disorder of the muscles of articulation and may be due to flaccid or spastic paralysis, rigidity, repetitive spasms (stuttering), or ataxia. The terms *dysarthria* and *anarthria* are applied to this category of speech disorder.
4. An alteration or loss of voice due to a disorder of the larynx or its innervation—*aphonia* or *dysphonia*. Articulation and language are unaffected.

The important category of *developmental disorders of speech and language* is considered fully in Chap. 28.

**Clinical Varieties of Aphasia**

Systematic examination will usually enable one to decide whether a patient has a predominantly (1) motor or Broca’s aphasia, sometimes called “expressive,” “anterior,” or “nonfluent” aphasia; (2) a *sensory* or Wernicke’s aphasia, referred to also as “receptive,” “posterior,” or “fluent” aphasia; (3) a total or *global* aphasia, with loss of all or nearly all speech and language functions; or (4) one of the *disconnection language syndromes*, such as conduction aphasia, word-deafness (auditory verbal agnosia), and word-blindness (visual verbal agnosia or alexia). There is in addition a condition of mutism, or a complete absence of verbal output, but this syndrome does not permit one to predict the exact locus of the lesion. *Anomia* (also called *nominal* or *anamnesic* aphasia) and the impaired ability to communicate by writing (*agraphia*) are found to some degree in practically all types of aphasia. As for agraphia, it only rarely exists alone. These main aphasic syndromes are summarized in Table 23-1.

**Broca’s Aphasia** Although a precise entity that conforms to what is commonly called Broca’s aphasia remains somewhat in doubt, we apply the term, as have others, to a primary deficit in language output or speech production, with relative preservation of comprehension. There is a wide range of variation in the motor speech deficit, from the mildest poverty of speech and so-called cortical dysarthria with entirely intact comprehension and ability to write (Broca’s area aphasia; “mini-Broca”) to a complete loss of all means of linguistic, phonetic, and gestural communication. Since the muscles that can no longer be used in speaking may still function in other learned acts—i.e., they are not paralyzed—the term *apraxia* seems apt but is imprecisely applied to certain elements of this deficit since it is not actually the loss of a previously learned ability.

In the most advanced form of the syndrome, patients lose all power of speaking aloud. Not a word can be uttered in conversation, in attempting to read aloud, or in trying to repeat words that are heard. One might suspect that the lingual and phonatory apparatus is paralyzed, until patients are observed to have no difficulty chewing, swallowing, clearing the throat, crying or shouting, and even vocalizing without words. Occasionally, the words *yes* and *no* can be uttered, usually in the correct context. Or patients may repeat a few stereotyped utterances over and over again, as if compelled to do so—a disorder referred to as *monophasia* (Critchley), *recurring utterance* (Hughlings Jackson), *verbal stereotypy*, or verbal automatism. If speech is possible at all, certain habitual expressions, such as “hi,” “fine, thank you,” or “good morning,” seem to be the easiest to elicit, and the words of well-known songs may be sung, or counting by consecutive numbers may remain facile. When angered or excited, the patient may utter an expletive, thus emphasizing the fundamental distinction between proposi-

^a Lesion in dominant (left) hemisphere unless noted.

tional and emotional speech (see above). The patient recognizes his ineptitude and mistakes. Repeated failures in speech cause exasperation or despair.

As a result of damage to the adjacent prerolandic motor area, the arm and lower part of the face are usually weak on the right side, and occasionally the leg as well. The tongue may deviate away from the lesion, i.e., to the right, and be slow and awkward in rapid movements. For a time, despite the relative preservation of auditory comprehension and the ability to read, commands to purse, smack, or lick the lips or to blow and whistle make other purposeful movements poorly executed, which signifies that an apraxia has extended to certain other learned acts involving the lips, tongue, and pharynx. In these circumstances, imitation of the examiner’s actions with orofacial muscles is performed better than execution of acts on command. Self-initiated actions, by contrast, may be normal. By implication from imaging findings in patients with apractic speech, the co-ordination of orobuccolingual movements, which are responsible for articulation, takes place in the left insular cortex (see Dronkers) rather than primarily in the Broca’s area. Scanning by positron emission tomography (PET) shows activation of the insular region as well as of the lateral premotor cortex and the anterior pallidum during repetition of single words (Wise et al). It would be incorrect, however, to conclude from these studies that Broca’s area itself does not participate in the composition of articulatory movements during natural speech.

In the milder form of Broca’s aphasia and in the recovery phase of the severe form, patients are able to speak aloud to some degree, but the normal melody of speech is entirely lacking. Words are uttered slowly and laboriously and enunciated poorly. Missing is the normal inflection, intonation, phrasing of words in a series, and pacing of word utterances. The overall impression is one of a lack of fluency, a term that has come to be almost synonymous with aphasia that derive from damage in and around the Broca’ area. This labored, uninflected speech stands in contrast to the fluent speech of Wernicke’s aphasia.

Speech in Broca’s aphasia is sparse (10 to 15 words per minute as compared with the normal 100 to 115 words per minute) and consists mainly of nouns, transitive verbs, or important adjectives; phrase length is abbreviated and many of the small words (articles, prepositions, conjunctions) are omitted, giving the speech a telegraphic character (so-called agrammatism). The substantive content of the patient’s language permits the crude communication of ideas, sometimes despite gross expressive difficulties. Repetition of the examiner’s spoken language is as abnormal as the patient’s own speech. If a patient with nonfluent Broca’s aphasia has no difficulty in repetition, the condition is termed transcortical motor aphasia (see further on).

Most patients with Broca’s aphasia have a correspondingly severe impairment in writing. Should the right hand be paralyzed, the patient cannot print with the left one, and if the right hand is
sparing, the patient fails as miserably in writing to request and replying to questions in written form. Letters are malformed and words misspelled. While writing to dictation is impossible, letters and words can still be copied. The dysgraphia usually corresponds in degree to the severity of the spoken disturbance, but there are exceptions in which one is far more affected.

The comprehension of spoken and written language, though seemingly normal under casual conditions, is usually defective in Broca’s aphasia and will break down under stringent testing, especially when novel or complicated material is introduced. The naming of objects and particularly parts of objects is particularly faulty. These are the most variable and controversial aspects of Broca’s aphasia, since in some patients with a loss of motor speech and agraphia as a result of cerebral infarction, the understanding of spoken and written language may be virtually normal. Mohr has pointed out that in such patients an initial mutism is usually replaced by a rapidly improving dyspraxic and effortful articulation, leading to complete recovery (a “mini-Broca’s aphasia,” in his terms). The lesion in such cases is restricted to a zone in and immediately around the posterior part of the inferior frontal convolution (Broca’s area per se). Mohr has stressed the distinction between this relatively mild and restricted type of motor speech disorder and the more complex syndrome that is traditionally referred to as Broca’s aphasia. The lesion in the major form of Broca’s aphasia is much larger than originally described, involving not only the inferior frontal gyrus but also the subjacent white matter and even the head of the caudate nucleus and putamen (Fig. 23-2), the anterior insula, frontoparietal operculum, and adjacent cerebral cortex. (The term operculum refers to the cortex that borders the sylvian fissure and covers or forms a lid over the insula, or island of Reil.) In other words, the lesion in the usual form of Broca’s aphasia extends well beyond the so-called Broca’s area (Brodman’s areas 44 and 45). Furthermore, persistence of Broca’s aphasia is associated with the larger type of lesion, illustrated in Fig. 23-2.

It is noteworthy that in one of Broca’s original patients, whose expressive language had been limited to a few verbal stereotypes for 10 years before his death, inspection of the surface of the brain (the brain was never cut, although CT scans have since been made) disclosed an extensive lesion encompassing the left insula; the frontal, central, and parietal operculum; and even part of the inferior parietal lobe posterior to the sylvian fissure. The Wernicke’s area was spared, refuting the prediction at the time of Marie. Inexplicably, Broca attributed the aphasic disorder to the lesion of the frontal operculum alone. Broca ignored the rest of the lesion, which he considered to be a later spreading effect of the stroke. Perhaps he was influenced by the prevailing opinion of the time (1861) that articulation was a function of the inferior parts of the frontal lobes. The fact that Broca’s name later became attached to a discrete part of the inferior frontal cortex helped to entrench the idea that Broca’s aphasia equated with a lesion in the Broca’s area. However, as pointed out above, a lesion confined only to this area gives rise to a relatively modest and transient motor speech disorder (Mohr et al) or to no disorder of speech at all (Goldstein).

Motor speech disorders, both severe Broca’s aphasia and the more restricted and transient types, are most often due to a vascular lesion. Embolic infarction in the territory of the upper (rolandic, superior) division of the middle cerebral artery is the most frequent type of stroke and results in the most abrupt onset and sometimes the most rapid regression of aphasia (hours or days), depending on whether the ischemia proceeds to tissue necrosis. Even with the latter, however, ischemia around the zone of infarction causes a more extensive syndrome than one might expect from the infarct itself, i.e., the physiologic impairment initially exceeds the pathologic. Because of the distribution of the superior branch of the middle cerebral artery, there are frequently associated right-sided faciobrachial paresis and a left-sided manual-brachial apraxia (so-called sympathetic apraxia), due probably to interruption of the fibers that connect the left and right motor cortices. Atherosclerotic thrombosis, primary or metastatic tumor, subcortical hypertensive, traumatic or anticoagulant-induced hemorrhage, and seizure, should they involve the appropriate parts of the motor cortex, may also declare themselves by a Broca’s aphasia.

A closely related syndrome, pure word mutism (aphemia), causes the patient to wordless (mute) but leaves inner speech intact and writing undisturbed. Anatomically, this is believed to lie in the nature of a disconnection of the motor cortex for speech from lower centers and is described with the dissociative speech syndromes discussed further on in this chapter.

Wernicke’s Aphasia This syndrome comprises two main elements: (1) an impairment in the comprehension of speech, basically an inability to differentiate word elements or phonemes, both spoken and written, and (2) a relatively fluent but paraphasic speech (further defined below). The location of the lesion in cases of Wernicke’s aphasia is the left superior lateral temporal lobe near the primary auditory cortex reveals the major role of the auditory region in the regulation of language. The defect in language is manifest further by a varying inability to repeat spoken and written

![Figure 23-2. Cerebral structures concerned with language output and articulation. B5 Broca’s area; C5 pre- and postcentral gyri; S3 striatum. Areas 43, 44, and 45 are Brodmann’s cytoarchitectonic areas. A lesion in any one of the components of this output network (B, C, or S) can produce a mild and transient Broca’s aphasia. Large lesions, damaging all three components, produce severe, persistent Broca’s aphasia with sparse, labored, agrammatic speech but well-preserved comprehension. (Illustration courtesy of Dr. Andrew Kertesz.)](https://example.com)
words. The involvement of visual association areas or their separation from the primary visual cortices is a common accompaniment that is reflected in an inability to read (alexia).

In contrast to Broca’s aphasia, the patient with Wernicke’s aphasia talks volubly, gestures freely, and appears strangely unaware of his deficit. Speech is produced mostly without effort; the phrases and sentences appear to be of normal length and are properly intoned and articulated. These attributes, in the context of aphasic disturbances, are referred to, as already mentioned, as “fluency” of speech. Despite the fluency and normal prosody, the patient’s speech is remarkably devoid of meaning. The patient with Wernicke’s aphasia produces many nonsensical words, and the words themselves are often malformed or inappropriate, a disorder referred to as paraphasia. A phoneme (the minimal unit of sound recognizable as language) or a syllable may be substituted within a word (e.g., “The grass is green”); this is called literal paraphasia. The substitution of one word for another (“The grass is blue”) is called verbal paraphasia or semantic substitution and is even more characteristic of Wernicke’s aphasia. Neologisms—i.e., syllables or words that are not part of the language—may also appear (“The grass is grumps”). Fluent, paraphasic speech may be entirely incomprehensible (gibberish or jargon aphasia). Fluency, however, is not an invariable feature of Wernicke’s aphasia. In some patients speech may be hesitant, in which case the block tends to occur in the part of the phrase that contains the central communicative (predicative) item, such as a key noun, verb, or descriptive phrase. The patient with such a disorder conveys the impression of constantly searching for the correct word and of having difficulty in finding it.

Although the motor apparatus required for the expression of language is intact, patients with Wernicke’s aphasia have great difficulty in functioning as social organisms because they are deprived of the main means of communication. They cannot understand fully what is said to them; a few simple commands may still be executed, but there is failure to carry out complex ones. They cannot read aloud or silently with comprehension, tell others what they want or think, or write spontaneously. Written letters are often combined into meaningless words, but there may be a scattering of correct words. In trying to designate an object that is seen or felt, they cannot find the name, even though they can sometimes repeat it from dictation; nor can they write from dictation the very words that they can copy. The copying performance is notably slow and laborious and conforms to the contours of the model, including the examiner’s handwriting style. All these defects, of course, are present in varying degrees of severity. In general, the disturbances in reading, writing, naming, and repetition parallel in severity the impairment in comprehension. There are, however, exceptions in which either reading or the understanding of spoken language is disproportionately affected. Some aphasiologists thus speak of two Wernicke syndromes.

In terms of the Broca-Wernicke schema, the motor language areas are no longer under control of the auditory and visual areas. The disconnection of the motor speech areas from the auditory and visual ones accounts for the impairment of repetition and the inability to read aloud. Reading may remain fluent, but with the same paraphasic errors that mar conversational language. The occurrence of dyslexia (impaired visual perception of letters and words) with lesions in the temporal lobe is explained by the fact that most individuals learn to read by transforming the printed word into the auditory form before it can gain access to the integrative centers in the posterior perisylvian region. Only in the congenitally deaf is there thought to be a direct pathway between the visual and central integrative language centers.

Wernicke’s aphasia that is due to stroke usually improves in time, sometimes to the point where the deficits can be detected only by asking the patient to repeat unfamiliar words, to name unusual objects or parts of objects, to spell difficult words, or to write complex self-generated sentences. A more favorable prognosis attends those forms in which some of the elements, e.g., reading, are only slightly impaired from the outset.

As discussed earlier, the term Wernicke’s area has been applied to the posterior part of area 22 in the most lateral part of the planum temporale. As a rule, in Wernicke’s aphasia the lesion lies in the posterior perisylvian region (comprising posterosecondary temporal, opercular supramarginal, angular, and posterior insular gyri) and is usually due to embolic (less often thrombotic) occlusion of the lower (inferior) division of the left middle cerebral artery. A hemorrhage confined to the subcortex of the temporoparietal region or involvement of this area by tumor, abscess, or extension of a small putamenal or thalamic hemorrhage may have similar effects but a better prognosis. A lesion that involves structures deep to the posterior temporal cortex will cause an associated homonymous quadrant- or hemianopia. Usually, there is no associated weakness of limbs or face and the fluently aphasic patient may be misdiagnosed as psychotic, especially if there is jargon aphasia. According to Kertesz and Benson, persistence of Wernicke’s aphasia is related to a lesion that involves both the supramarginal and angular gyri.

The posterior perisylvian region appears to encompass a variety of language functions, and seemingly minor changes in the size and locale of the lesion are associated with important variations in the elements of Wernicke’s aphasia or lead to conduction aphasia or to pure word-deafness (see below). The interesting theoretical problem is whether all the deficits observed are indicative of a unitary language function that resides in the posterior perisylvian region or, instead, of a series of separate sensorimotor activities whose anatomic pathways happen to be crowded together in a small region of the brain. In view of the multiple ways in which language is learned and deteriorates in disease, the latter hypothesis seems more likely.

**Global, or Total, Aphasia** This syndrome is due to destruction of a large part of the language zone, embracing both Broca’s and Wernicke’s areas and much of the territory between them. The lesion is usually due to occlusion of the left internal carotid artery or proximal middle cerebral artery, but it may be caused by hemorrhage, tumor, or other lesions, and briefly as a postictal effect.

All aspects of speech and language are affected. At most, the patients can say only a few words, usually some cliché or habitual phrase, and they can imitate single sounds. Or they can only emit a syllable, such as “ah,” or cry, shout, or moan. Many are initially mute. They may understand a few words and phrases, but—because of rapid fatigue and verbal and motor perseveration (the obligatory repetitiveness of a word or motor act just after it has been employed)—they characteristically fail to carry out a series of simple commands or to name a series of objects. They cannot read or write or repeat what is said to them. The patient may participate in common gestures of greeting, show modesty and avoidance reactions, and engage in self-help activities. With the passage of time, some degree of comprehension of language may return, and the clinical picture that is then most likely to emerge is closest to that of a severe Broca’s aphasia.
Almost invariably, a degree of right hemiplegia, hemianesthesia, and homonymous hemianopia accompanies global aphasia of vascular origin. In such patients, language function rarely recovers to a great degree. On the other hand, improvement frequently occurs when the main cause is cerebral trauma, compression from edema, postconvulsive paralysis, or a transient metabolic derangement such as hypoglycemia, hyponatremia, etc., which may worsen the aphasia of an old lesion that had involved language areas.

Disconnection Syndromes

(See also Chap. 22.)

This term refers to certain disorders of language that result not from lesions of the cortical language areas themselves but from an apparent interruption of association pathways joining the primary receptive (sensory) areas to the language areas. Included also in this category are aphasias due to lesions that separate the more strictly receptive parts of the language mechanism itself from the purely motor ones (conduction aphasia—see below) and to lesions that isolate the perisylvian language areas, separating them from the other parts of the cerebral cortex (transcortical aphasias).

The anatomic basis for most of these so-called disconnection syndromes is poorly defined. The theoretical concept, however, is an interesting one and emphasizes the importance of afferent, intercortical, and efferent connections of the language mechanisms. The weakness of the concept is that it may lead to premature acceptance of anatomic and physiologic mechanisms that are overly simplistic. The locale of the lesion that causes loss of a language function does not localize the language function itself, a warning enunciated long ago by Hughlings Jackson. Nevertheless, the language disorders described below occur with sufficient regularity and clinical uniformity to be as useful as the more classic and common types of aphasia in revealing the complexity of language functions.

Conduction Aphasia As indicated earlier, Wernicke theorized that certain clinical symptoms would follow a lesion that effectively separated the auditory and motor language areas without directly damaging either of them. Since then, a number of well-studied cases have been described that conform to his proposed model of Leitungsaphasie (conduction aphasia), which is the name he gave it. The characteristic feature is one of severely impaired repetition; the defect applies to both single words and nonwords. The second essential feature is an affected but relatively preserved comprehension in comparison to Wernicke’s aphasia.

In other respects, the features of conduction aphasia resemble those of a mild Wernicke’s aphasia. There is a similar fluency and paraphasia in self-initiated speech, in repeating what is heard, and in reading aloud; writing is invariably impaired. Dysarthria and dysprosody are usually lacking. Speech output is normal or somewhat reduced. As mentioned, comprehension is by no means perfect, but compared with one who has Wernicke’s aphasia, the patient with conduction aphasia has relatively little difficulty in understanding words that are heard or seen and is aware of his deficit.

The lesion in the few autopsied cases has been located in the cortex and subcortical white matter in the upper bank of the left sylvian fissure, usually involving the supramarginal gyrus and occasionally the most posterior part of the superior temporal region. The reason for classifying this aphasia as a disconnection syndrome is the not entirely correct notion articulated by Damasio and Geschwind, that Wernicke’s and Broca’s areas are spared, and the critical structure involved is the arcuate fasciculus. This fiber tract streams out of the temporal lobe, proceeding somewhat posteriorly, around the posterior end of the sylvian fissure; there it joins the superior longitudinal fasciculus, deep in the anteroinferior parietal region, and proceeds forward, deep to the suprasylvian operculum, to the motor association cortex, including the Broca’s and Exner’s areas (see Fig. 22-7). However, in most of the reported cases, including those described by the Damasios, the left auditory complex, insula, and supramarginal gyrus were also involved. In any case, the usual cause of conduction aphasia is an embolic occlusion of the ascending parietal or posterior temporal branch of the middle cerebral artery, but other forms of vascular disease, neoplasm, or trauma in this region may produce the same syndrome.

The concept of conduction aphasia, as outlined above, remains a useful theoretic construct, although not all authors are in agreement as to its purity as an aphasic syndrome. Mohr, in his analysis of the writings on this subject, found that the distinction between conduction aphasia and Wernicke’s aphasia, mainly one of degree of auditory comprehension, was ambiguous clinically and that the underlying lesions in the two syndromes were much the same. A summary of the arguments against a subcortical disconnection and those favoring a cortical origin can be found in the report of the condition with focal seizures by Anderson and colleagues.

“Pure” Word-Deafness This uncommon disorder, originally described by Lichtheim in 1885, is characterized by an impairment of auditory comprehension and repetition and an inability to write to dictation. Self-initiated utterances are usually correctly phrased but sometimes paraphasic; spontaneous writing and the ability to comprehend written language are preserved, thus distinguishing this disorder from classic Wernicke’s aphasia. Patients with pure word-deafness may declare that they cannot hear, but shouting does not help, sometimes to their surprise. Audiometric testing and auditory evoked potentials disclose no hearing defect, and nonverbal sounds, such as a doorbell, can be heard without difficulty. The patient is forced to depend heavily on visual cues and frequently uses them well enough to understand most of what is said. However, tests that prevent the use of visual cues readily uncover the deficit. If able to describe the auditory experience, the patient says that words sound like a jumble of noises. As in the case of visual verbal agnosia (see below), the syndrome of pure auditory verbal agnosia is not pure, particularly at its onset, and paraphasic and other elements of Wernicke’s aphasia may be detected (Buchman et al). At times this syndrome is the result of resolution of a more typical Wernicke’s aphasia, and it will be recognized that word-deafness is an integral feature of many instances of Wernicke’s aphasia. Conceptually it has been thought of as an exclusive injury of the auditory processing system.

In most recorded autopsy studies, the lesions have been bilateral, in the middle third of the superior temporal gyri, in a position to interrupt the connections between the primary auditory cortex in the transverse gyri of Heschl and the association areas of the superoposterior cortex of the temporal lobe. In a few cases unilateral lesions have been localized in this part of the dominant temporal lobe (see page 397). Requirements of small size and superficiality of the lesion in the cortex and subcortical white matter are best fulfilled by an embolic occlusion of a small branch of the lower division of the middle cerebral artery.
“Pure” Word-Blindness (Alexia without Agraphia, Visual Verbal Agnosia) This is a not uncommon syndrome, in which a literate person loses the ability to read aloud, to understand written script, and, often, to name colors—i.e., to match a seen color to its spoken name—visual verbal color anomia. Such a person can no longer name or point on command to words, although he is sometimes able to read letters or numbers. Understanding spoken language, repetition of what is heard, writing spontaneously and to dictation, and conversation are all intact. The ability to copy words is impaired but is better preserved than reading, and the patient may even be able to spell a word or to identify a word by having it spelled to him or by reading one letter at a time (letter-by-letter reading). In some cases, the patient manages to read single letters but not to join them together (asyllabia). The most striking feature of this syndrome is the retained capacity to write fluently, after which the patient cannot read what has been written (alexia without agraphia). When the patient with alexia also has difficulty in auditory comprehension and in repeating spoken words, the syndrome corresponds more closely to Wernicke’s aphasia.

Autopsies of such cases have usually demonstrated a lesion that destroys the left visual cortex and underlying white matter, particularly the geniculocalcine tract, as well as the callosal connections of the right visual cortex with the intact language area of the dominant hemisphere (page 409). In the case originally described by Dejerine (1892), the disconnection occurred in the posterior part (splenium) of the corpus callosum, wherein lie the connections between the visual association areas of the two hemispheres (see Fig. 22-6). More often the callosal pathways are interrupted in the forceps major or in the paraventricular region (Damasio and Damasio). In either event, the patient is blind in the right half of each visual field by virtue of the left occipital lesion, and visual information reaches only the right occipital lobe; however, this information cannot be transferred, via the callosal pathways, to the language area of the left hemisphere.

A rare variant of this syndrome takes the form of alexia without agraphia and without hemianopia. A lesion deep in the white matter of the left occipital lobe, at its junction with the parietal lobe, interrupts the projections from the intact (right) visual cortex to the language areas but spares the geniculocalcine pathway (Greenblatt). This lesion, coupled with one in the splenium, prevents all visual information from reaching the language areas, including the angular gyrus and Wernicke’s area.

In yet other cases, the lesion is confined to the angular gyrus or the subjacent white matter. In such cases also, a right homonymous hemianopia will be absent, but the alexia may be combined with agraphia and other elements of the Gerstmann syndrome—i.e., right-left confusion, acalculia, and fingeragnosia (page 402). This constellation of symptoms is sometimes referred to as the syndrome of the angular gyrus. Anomic aphasia may be added (see below).

“Pure” Word Mutism (Aphemia, Pure Motor Aphasia of Déjerine) Occasionally, as a result of a vascular lesion or another type of localized injury of the dominant frontal lobe, the patient loses all capacity to speak while retaining perfectly the ability to write, to understand spoken words, to read silently with comprehension, and to repeat spoken words. Right facial and brachial paresis may be associated. From the time speech becomes audible, language may be syntactically complete, showing neither loss of vocabulary nor agrammatism; or there may be varying degrees of dysarthria (hence “cortical dysarthria”), anomia, and paraphasic substitutions, especially for consonants. The most notable feature of this type of speech disorder is its transience: within a few weeks or months, language is restored to normal. Bastian and more recently other authors have called this syndrome aphemia, a term that was used originally by Broca in another context—to describe the severe motor aphasia that now carries his name. Probably the syndrome is closely allied to the “mini-Broca’s aphasia” described on page 417.

The anatomic basis of pure word mutism has not been determined precisely. In a few postmortem cases, reference is made to a lesion in Broca’s area. Damasio and Geschwind have stated that the lesion is anterior and superior to this area. A well-studied case has been reported by Roch-LeCours and Lhermitte. Their patient uttered only a few sounds for 4 weeks, after which he recovered rapidly and completely. From the onset of the stroke, the patient showed no disturbance of comprehension of language or of writing. Autopsy disclosed an infarct that was confined to the cortex and subjacent white matter of the lowermost part of the precentral gyrus; Broca’s area, one gyrus forward, was completely spared. Other cases have involved mainly Broca’s area.

Anomic (Amnesic, Nominal) Aphasia Some degree of word-finding difficulty is probably part of every type of language disorder, including that which occurs with the confusional states and dementia. In fact, without an element of anomia, a diagnosis of aphasia is usually incorrect. Only when this feature is the most notable aspect of language difficulty is the term anomic aphasia employed. In this latter condition, a relatively uncommon form of aphasia, the patient loses only the ability to name people and objects. There are typical pauses in speech, groping for words, circumlocution, and substitution of another word or phrase that is intended to convey the meaning. Perseveration may be prominent. Or the patient may simply fail to name a shown object, in contrast to the usual aphasic patient, who produces a paraphasic error. Less frequently used words give more trouble. When shown a series of common objects, the patient may tell of their use, or demonstrate the same, instead of giving their names. The difficulty applies not only to objects seen but to the names of things heard or felt (Geschwind), but this is more difficult to demonstrate. In addition to displaying normal fluency of spontaneous speech and preserved comprehension and repetition, the patients we have seen with anomic aphasia have been surprisingly adept in spelling.

Beauvois and coworkers have described a form of bilateral tactile aphasia due to a left parieto-occipital lesion in which objects seen and verbally mentioned could be named, but not those felt with either hand. Recall of the names of letters, digits, and other printed verbal material is almost invariably preserved, and immediate repetition of a spoken name is intact. That the deficit is principally one of naming is shown by the patient’s correct use of the object and, usually, by an ability to point to the correct object on hearing or seeing the name and to choose the correct name from a list. The patient’s understanding of what is heard or read is normal. There is a tendency for patients to attribute their failure to forgetfulness or to give some other lame excuse for the disability, suggesting that they are not completely aware of the nature of their difficulty.

Of course, there are patients who fail not only to name objects but also to recognize the correct word when it is given to them. In such patients, the understanding of what is heard or read is not normal, i.e., the naming difficulty is but one symptom of another type of aphasic disorder.
Anomic aphasia has been associated with lesions in different parts of the language area, classically in the left temporal lobe. In these cases the lesion has been deep in the basal portion of the posterior temporal lobe or in the middle temporal convolution, in position to interrupt connections between sensory language areas and the hippocampal regions concerned with learning and memory. Mass lesions—such as a tumor, herpes encephalitis, or an abcess—are the most frequent causes; as these lesions enlarge, a contralateral upper quadratic visual field defect or a Wernicke’s aphasia is added. Occasionally, anomia appears with lesions due to occlusion of the temporal branches of the posterior cerebral artery, and it’s in these instances that we have seen the most dramatic cases, usually associated with a right hemianopia and alexia but normal writing ability. Anomia may be a prominent manifestation of transcortical motor aphasia (see below) and may be associated with the Gerstmann syndrome, in which case the lesions are found in the frontal lobe and angular gyrus, respectively. An anomic type of aphasia is often an early sign of Alzheimer and Pick disease (minor degrees of it are common in old age) and is a principal feature of a number of the degenerative lobar cerebral atrophies (see Chap. 39). Finally, anomic aphasia may be the only residual abnormality after partial recovery from Wernicke’s, conduction, and the hippocampal regions concerned with learning and memory. This locale explains the frequent concurrence of transient visual agnosia and hemianopia. In general, this disorder has a good prognosis.

Presumably, in transcortical sensory aphasia, information from the nonlanguage areas of the cerebrum cannot be transferred to Wernicke’s area for conversion into verbal form. The paraphasia is thought to result from the weakened control of the motor language areas by the auditory and visual areas, though the direct connection between them, presumably the arcuate fasciculus, is preserved. Preservation of this direct connection is said to account for the ability to repeat. Reading and auditory comprehension suffer because the sensory information does not reach the central integrative centers.

In transcortical motor aphasia (“anterior isolation syndrome,” “dynamic aphasia” of Luria) the patient is unable to initiate conversational speech, producing only a few grunts or syllables. Comprehension is relatively preserved, but repetition is strikingly intact, distinguishing this syndrome from pure word mutism (see above). Transcortical motor aphasia occurs in two clinical contexts: (1) in a mild or partially recovered Broca’s aphasia in which repetition remains superior to conversational speech (repeating and reading aloud are generally easier than self-generated speech) and (2) in states of abulia and akinetic mutism with frontal lobe damage, for the same reason. Several of our cases have resulted from infarctions in the watershed zone between the anterior and middle cerebral arteries, after cardiac arrest or shock.

These transcortical syndromes are of great theoretical interest and are probably more common than is currently appreciated.

**Foreign Accent Syndrome** This rare but peculiar (and somewhat amusing) condition defies classification but is worthy of comment because it may be mistaken for hysteria or psychosis. An accent that is vague but distinctly foreign replaces the patient’s native language. The syndrome arises after a left-sided lesion, most often a stroke; and a mild Broca’s aphasia is usually associated. Although the accent may be interpreted by the listener as compatible with German, Spanish, French, Asian, or another nationality, authoritative analysis of the speech pattern indicates that the alterations are not specific to any genuine language and are simply attributed by the listener to a known foreign accent. Usually this aberration is encountered as a transient phenomenon during recovery from stroke. The relation to disorders of prosody is unclear. An extensive analysis of one case and references can be found in the article by Kurowski and colleagues.

**The Agraphias**

Writing is, of course, an integral part of language function, but a less essential and universal component, for a considerable segment of the world’s population speaks but does not read or write. It might be supposed that all the rules of language derived from the study of aphasia would be applicable to agraphia. In large part this is true. One must be able to formulate ideas in words and phrases in order to have something to write as well as to say; hence disorders of writing, like disorders of speaking, reflect all the basic defects of language. But there is an obvious difference between these two expressive modes. In speech, only one final motor pathway coordinating the movements of lips, tongue, larynx, and respiratory muscles is available, whereas if the right hand is paralyzed, one can still write with the left one, or with a foot, and even with the mouth by holding a pencil between the teeth.

The writing of a word can be accomplished either by the direct lexical method of recalling its spelling or by sounding out its phonemes and transforming them into learned graphemes (motor images)—i.e., the phonologic method. Some authors state that in agraphia there is a specific difficulty in transforming phonologic information, acquired through the auditory sense, into orthographic forms; others see it as a block between the visual form of phonemes and the cursive movements of the hand (Basso et al). In support of the latter idea is the fact that reading and writing usually develop together and are long preceded by the development and elaboration of auditory-articular mechanisms.

Pure agraphia as the initial and sole disturbance of language function is a great rarity, but such cases have been described, as summarized in the review of Rosati and de Bastiani. Pathologically verified cases are virtually nonexistent, but CT examination of this case disclosed a lesion of the posterior perisylvian area. This is in keeping with the observation that a lesion in or near the angular
A lesion of the dominant thalamus, usually vascular and involving the posterior nuclei, may cause an aphasia, the clinical features of which are not entirely uniform. Usually there is mutism initially and comprehension is impaired. During the early phases of recovery, spontaneous speech is reduced in amount; less often, speech is fluent and paraphasic to the point of jargon. Reading and writing may or may not be affected. Anomia has been described with a ventrolateral thalamic lesion (Ojemann). Characteristically, the patient’s ability to repeat dictated words and phrases is unimpaired, (transcortical sensory aphasia). Complete recovery in a matter of weeks is the rule.

Aphasia has also been described frequently with dominant striatocapsular lesions, particularly if they extend laterally into the subcortical white matter of the temporal lobe and insula. The head of the caudate, anterior limb of the internal capsule, or the anteromesial aspect of the putamen are the structures involved in different patients. The aphasia is characterized by nonfluent, dysarthric, paraphasic speech and varying degrees of difficulty with comprehension of language, naming, and repetition. The lesion is vascular as a rule, and a right hemiparesis is usually associated. In general, striatocapsular aphasia recovers more slowly and less completely than thalamic aphasia.

These two subcortical aphasias—thalamic and striatocapsular—resemble but are not identical to the Wernicke and Broca types of aphasia. For further discussion, the reader is directed to the articles of Naeser and of Alexander and their colleagues.

Other Cerebral Disorders of Language

It would be incorrect to conclude that the syndromes described above, all of which are related to perisylvian lesions of the dominant cerebral hemisphere, represent all the ways in which cerebral disease disturbs language. The effects on speech and language of diffuse cerebral disorders, such as delirium tremens and Alzheimer disease, have already been mentioned (see pages 364 and 417). Pathologic changes in parts of the cerebrum other than the perisylvian regions may secondarily affect language function. The lesions that occur in the border zones between major cerebral arteries and effectively isolate perisylvian areas from other parts of the cerebrum fall into this category (transcortical aphasias, see above). Other examples are the lesions in the medio-orbital or superior and lateral parts of the frontal lobes, which impair all motor activity, to the point of abulia or akinetiform mutism (page 359). The mute patient, in contrast to the aphasic one, emits no sounds. If the patient is less severely hypokinetic, his speech tends to be laconic, with long pauses and an inability to sustain a monologue. Extensive occipital lesions will, of course, impair reading, but they also reduce the utilization of all visual and lexical stimuli. Deep cerebral lesions, by causing fluctuating states of inattention and disorientation, induce fragmentation of words and phrases and sometimes protracted, uncontrollable talking (logorrhea).

Also common in global or multifocal cerebral diseases are defects in prosody, both expressive and receptive. These appear in numerous states that affect global cerebral function, such as Alzheimer disease as well as with lesions of the nondominant (right) perisylvian region as noted in Chap. 22.

Severe mental retardation often results in failure to acquire even spoken language, as pointed out in Chaps. 28 and 38. If there is any language skill, it consists only of the understanding of a few simple spoken commands. The subject of developmental dyslexia is discussed on page 510.

Approach to the Patient with Language Disorders

In the investigation of aphasia, it is first necessary to inquire into the patient’s native language, handedness, and previous level of literacy and education. For many years it has been taught that following the onset of aphasia, individuals who had been fluent in more than one language (polyglots) improved more quickly in their native language than in a subsequently acquired one (a derivative of Ribot’s law of retained distant memory). This rule seems to hold
if the patient is not truly fluent in the more recently acquired language or has not used it for a long time. More often, the language most used before the onset of the aphasia will recover first (Pitres’ law). Usually, if adequate testing is possible, more or less the same aphasic abnormalities are found in both the first and the more recently acquired language.

Many naturally left-handed children are trained to use the right hand for writing; therefore, in determining handedness, one must ask which hand is preferred for throwing a ball, threading a needle, sewing, or using a tennis racket or hammer, and which eye is used for sighting a target with a rifle or other instrument. It is important, before beginning the examination, to determine whether the patient is alert and can participate reliably in testing, since accurate assessment of language depends on these factors.

One should quickly ascertain whether the patient has other gross signs of a cerebral lesion such as hemiplegia, facial weakness, homonymous hemianopia, or corticospinal loss. When a constellation of these major neurologic signs is present, the aphasic disorder is usually of the total (global) type. A right brachiofacial paralysis aligns with Broca’s aphasia; in contrast, a restricted right hemianopia—or quadrantopia—is a common accompaniment of Wernicke’s aphasia, and hemiparesis is absent. Dyspraxia of limbs and speech musculature in response to spoken commands or to visual mimicry is generally associated with Broca’s aphasia and sometimes with Wernicke’s aphasia. Bilateral or unilateral homonymous hemianopia without motor weakness tends often to be linked to pure word-blindness, to alexia with or without agraphia, and to anomia aphasia.

The bedside analysis of aphasic disorders that we find most useful entails the systematic testing of six aspects of language function: conversational speech, comprehension, repetition, reading, writing, and naming. Simply engaging the patient in conversation permits assessment of the motor aspects of speech (praxis and prosody), fluency, and language formulation. If the disability consists mainly of sparse, laborious, nonfluent speech, it suggests, of course, Broca’s aphasia, and this possibility can be pursued further by tests of repeating from dictation and by special tests of praxis of the oropharyngeal muscles. Fluent but empty paraphasic speech with impaired comprehension is indicative of Wernicke’s aphasia. Impaired comprehension but perfectly normal formulated speech and intact ability to read suggest the rare syndrome of pure word-deafness.

When conversation discloses virtually no abnormalities, other tests may still be revealing. The most important of these are reading, writing, repetition, and naming. Reading aloud single letters, words, and text may disclose the dissociative syndrome of pure word-blindness. Except for this syndrome and pure word mutism (see above), writing is disturbed in all forms of aphasia. Literal and verbal paraphasic errors may appear in milder cases of Wernicke’s aphasia as the patient reads aloud from a text or from words in the examiner’s handwriting. Similar errors appear even more frequently when the patient is asked to explain the text, read aloud, or give an explanation in writing.

Testing the patient’s ability to repeat spoken language is a simple and important maneuver in the evaluation of aphasic disorders. As with other tests of aphasia, it may be necessary to increase the complexity of the test—from digits and simple words to complex words, phrases, and sentences—in order to disclose the full disability. Defective repetition occurs in all the major forms of aphasia (Broca’s, Wernicke’s, and global) due to lesions in the perisylvian language areas. The patient may be unable to repeat what is said to him, despite relatively adequate comprehension—the hallmark of conduction aphasia. Contrariwise, normal repetition in an aphasic patient (transcortical aphasia) indicates that the perisylvian area is largely intact. In fact, the tendency to repeat may be excessive (echolalia). Preserved repetition is also characteristic of anomic aphasia and occurs occasionally with subcortical lesions. Disorders confined to naming, other language functions (reading, writing, spelling, etc.) being adequate, are diagnostic of amnesic, or anomiac, aphasia and referable usually to lower temporal lobe lesions.

These deficits can be quantified by the use of any one of several examination procedures. Those of Goodglass and Kaplan (Boston Diagnostic Aphasia Examination, or BDAE) and of Kertesz (Western Aphasia Battery, or WAB) are the most widely used in the United States. The use of these procedures will enable one to predict the type and localization of the lesion in approximately two-thirds of the patients, which is not much better than detailed bedside examination. Using these tests, aphasia of the Broca, Wernicke, conduction, global, and anomiac types accounted for 392 of 444 unselected cases studied by Benson.

**Treatment**

The sudden onset of aphasia would be expected to cause great apprehension, but except for cases of pure or almost pure motor disorders of speech, most patients show remarkably little concern. It appears that the very lesion that deprives them of speech also causes at least a partial loss of insight into their own disability. This reaches almost a ludicrous extreme in some cases of Wernicke’s aphasia, in which the patient becomes indignant when others cannot understand his jargon. Nonetheless, as improvement occurs, many patients do become discouraged. Reassurance and a program of speech rehabilitation are the best ways of helping the patient at this stage.

Whether contemporary methods of speech therapy accomplish more than can be accounted for by spontaneous recovery is still uncertain. Most aphasic disorders are due to vascular disease and trauma, and they are nearly always accompanied by some degree of spontaneous improvement in the days, weeks, and months that follow the stroke or accident. A Veterans Administration Cooperative Study (Wertz et al) has suggested that intensive therapy by a speech pathologist does hasten improvement. Also, Howard and colleagues have shown increased efficacy of word retrieval in a group of chronic stable aphasics treated by two different techniques. More studies of this type, which control for the effects of the patient’s motivation and the interest of family and therapist, are needed. In an interesting personal experiment by Wender, a classic case who had become aphasic, practice of Greek vocabulary and grammar led to recovery in that language, but there was little recovery of her facility with Latin, which was not similarly exercised.

One must decide for each patient when speech training should be started. As a rule, therapy is not advisable in the first few days of an aphasic illness, because one does not know how severe or lasting it will be. Also, if the patient suffers a severe global aphasia and can neither speak nor understand spoken and written words, the speech therapist is virtually helpless. Under such circumstances, one does well to wait a few weeks until one of the language functions has begun to return. Then the physician and therapist can begin to help the patient to use that function to a maximum degree. In milder aphasic disorders, the patient may be sent to the speech therapist as soon as the illness has stabilized.

The methods of language rehabilitation are specialized, and it is advisable to call in a person who has been trained in this field.
DISORDERS OF ARTICULATION AND PHONATION

The act of speaking involves a highly coordinated sequence of actions of the respiratory musculature, larynx, pharynx, palate, tongue, and lips. These structures are innervated by the vagal, hypoglossal, facial, and phrenic nerves, the nuclei of which are controlled by both motor cortices through the corticobulbar tracts. As with all movements, those involved in speaking are subject to extrapyramidal influences from the cerebellum and basal ganglia. The act of speaking requires that air be expired in regulated bursts, and each expiration must be maintained long enough (by pressure mainly from the intercostal muscles) to permit the utterance of phrases and sentences. The current of expired air is then finely regulated by the activity of the various muscles engaged in speech.

Phonation, or the production of vocal sounds, is a function of the larynx, more particularly the vocal cords. The pitch of the speaking or singing voice depends upon the length and mass of the membranous parts of the vocal cords and can be varied by changing their tension; this is accomplished by means of the intrinsic laryngeal muscles, before any audible sound emerges. The controlled intrathoracic pressure forces air past the glottis and separates the margins of the cords, setting up a series of vibrations and recoils. Sounds thus formed are modulated as they pass through the nasopharynx and mouth, which act as resonators. Articulation consists of contractions of the pharynx, palate, tongue, and lips, which interrupt or alter the vocal sounds. Vowels are of laryngeal origin, as are some consonants, but the latter are formed for the most part during articulation; the consonants m, b, and p are labial, l and t are lingual, and nk and ng are guttural (throat and soft palate).

Defective articulation (dysarthria) and phonation (dysphonia) are recognized at once by listening to the patient speak during ordinary conversation or read aloud from a newspaper. Test phrases or attempts at rapid repetition of lingual, labial, and guttural consonants (e.g., la-la-la-la, me-me-me-me, or k-k-k-k) bring out the particular abnormality. Disorders of phonation call for a precise analysis of the voice and its apparatus during speech and singing. If necessary, the movements of the vocal cords should be inspected with a laryngoscope and those of the tongue, palate, and pharynx by direct observation.

Prognosis and Patterns of Recovery Some aspects of prognosis have been discussed above. In general, recovery from aphasia due to cerebral trauma is usually faster and more complete than that from aphasia due to stroke. The type of aphasia and particularly its initial severity (extent of the lesion) clearly influence recovery: global aphasia usually improves very little, and the same is true of severe Broca’s and Wernicke’s aphasias (Kertesz and McCabe). The various dissociative speech syndromes and pure word mutism tend to improve rapidly and often completely. Also, in general, the outlook for recovery from any particular aphasia is more favorable in a left-handed person than in a right-handed one. Characteristically, in the course of recovery, a severe aphasia of one type may evolve into another type (global into severe Broca’s; Wernicke’s, transcortical, and conduction into amnestic)—patterns of recovery that may mistakenly be attributed to the effects of therapy. It is in part because so many factors may influence the mode of recovery from aphasia that the effectiveness of formal speech therapy has never been fully evaluated.

Dysarthria and Anarthria

In pure dysarthria or anarthria, there is no abnormality of the cortical language mechanisms. The dysarthric patient is able to understand perfectly what is heard and, if literate, has no difficulty in reading and writing, although he may be unable to utter a single intelligible word. This is the strict meaning of being inarticulate. Defects in articulation may be subdivided into several types: lower motor neuron (neuromuscular); spastic (pseudobulbar); rigid (extrapyramidal); cerebellar-ataxic; and hypo- and hyperkinetic dysarthrias.

Lower Motor Neuron (Neuromuscular) Dysarthria, Atrophic Bulbar Paralysis This is due to weakness or paralysis of the articulatory muscles, the result of disease of the motor nuclei of the medulla and lower pons or their intramedullary or peripheral extensions (lower motor neuron paralysis). In advanced forms of this disorder, the shriveled tongue lies inert and fasciculating on the floor of the mouth, and the lips are lax and tremulous. Saliva constantly collects in the mouth because of dysphagia, and drooling is troublesome. Dysphonia—alteration of the voice to a rasping monotone due to vocal cord paralysis—is often added. As this condition evolves, speech becomes slurred and progressively less distinct. There is special difficulty in the enunciation of vibratives, such as r, and as the paralysis becomes more complete, lingual and labial consonants are finally not pronounced at all. In the past, bilateral paralysis of the palate, causing nasality of speech, often occurred with diphtheria and poliomyelitis, but now it occurs most often with progressive bulbar palsy, a form of motor neuron disease (page 940), and with certain other neuromuscular disorders, particularly myasthenia gravis. Bilateral paralysis of the lips—as in the facial diplegia of the Guillain-Barré syndrome or of Lyme disease—interferes with enunciation of labial consonants; p and b are slurred and sound more like f and v. Degrees of both of these abnormalities are also observed in myasthenia gravis.

Spastic (Pseudobulbar) Dysarthria Diseases that involve the corticobulbar tracts bilaterally—usually due to vascular, demyelinating, or motor system disease (amyotrophic lateral sclerosis)—result in the syndrome of spastic bulbar (pseudobulbar) palsy. The patient may have had a clinically inconstant vascular lesion at some time in the past, affecting the corticobulbar fibers on one side; however, since the bulbar muscles on each side are innervated by both motor cortices, there may be little or no impairment in speech or swallowing from a unilateral corticobulbar lesion. Should another stroke then occur, involving the other corticobulbar tract at the pontine, midbrain, or capsular level, the patient immediately becomes dysphagic, dysphonic, and anarthric or dysarthric, often with paresis of the tongue and facial muscles. This condition, unlike bulbar paralysis due to lower motor neuron involvement, entails no atrophy or fasciculations of the paralyzed muscles; the jaw jerk and other facial reflexes usually become exaggerated, the palatal reflexes are retained or increased, emotional control is impaired (spasmodic crying and laughing)—the pseudobulbar affective state.
described on page 445), and sometimes breathing becomes periodic (Cheyne-Stokes). Amyotrophic lateral sclerosis is the main condition in which the signs of spastic and atrophic bulbar palsy are combined.

When the dominant frontal operculum is damaged, speech may be dysarthric, usually without impairment in emotional control. In the beginning, with vascular lesions, the patient may be mute; but with recovery or in mild degrees of the same condition, speech is notably slow, thick, and indistinct, much like that of partial bulbar paralysis. Magnetic stimulation of the cortex in these cases reveals a delay in corticobulbar conduction. The terms cortical dysarthria and anarthria, among many others, have been applied to this disorder, which is more closely related to mild forms of Broca’s aphasia than to the dysarthrias being considered in this section (see “Pure Word Mutism,” page 422). Also, in many cases of partially recovered Broca’s aphasia and in the “mini-Broca” syndrome, the patient is left with a dysarthria that may be difficult to distinguish from a pure articulatory defect. Careful testing of other language functions, especially writing, will in this instance reveal the aphasic aspect of the defect.

A severe dysarthria that is difficult to classify but resembles that of cerebellar disease may occur with a left hemiplegia, usually the result of capsular or right opercular infarction. It tends to improve over several weeks but initially may be so severe as to make speech incomprehensible (Ropper).

Rigid (Extrapyramidal) Dysarthria In Parkinson and other extrapyramidal diseases associated with rigidity of muscles, one observes a rather different disturbance of articulation, characterized by rapid mumbling and cluttered utterance and slurring of words and syllables with trailing off in volume at the ends of sentences. The voice is low-pitched and monotonous, lacking both inflection and volume (hyponopia). The words are spoken hastily and run together in a pattern that is almost the opposite of the slowed pattern of spastic dysarthria. In advanced cases, speech is almost unintelligible; only whispering is possible. It may happen that the patient finds it impossible to talk while walking but can speak better if standing still, sitting, or lying down. The terms hypokinetic and festinating have been applied to these aspects of parkinsonian speech. Curiously, in the extrapyramidal disorder of progressive supranuclear palsy, the dysarthria and dysphonia tend to be spastic in nature.

With chorea and myoclonus, speech may also be affected in a highly characteristic way. The speech is loud, harsh, improperly stressed or accented, and poorly coordinated with breathing (hyperkinetic dysarthria). Unlike the defect of pseudobulbar palsy or Parkinson disease, chorea and myoclonus cause abrupt interruptions of the words by superimposition of involuntary movements of bulbar muscles. The latter abnormality is best described as “hic-cup speech,” in that the breaks are unexpected, as in singulation. Grimacing and other characteristic movement abnormalities must be depended upon for diagnosis. The Tourette syndrome of multiple motor and vocal tics is characterized both by startling vocalizations (barking noises, squales, shrieks, grunting, sniffing, snorting) and by speech disturbances, notably stuttering and the involuntary utterance of obscenities (coprolalia).

Elements of both corticobulbar (spastic) and extrapyramidal speech disturbances may be combined in Wilson disease, in Hallervorden-Spatz disease, and in the form of cerebral palsy called double athetosis. The speech is loud, slow, and labored; it is poorly coordinated with breathing and accompanied by facial contortions and athetotic accesses of tone in other muscles. In diffuse cerebral diseases such as general paresis, slurred, tremulous speech is one of the cardinal signs.

Ataxic Dysarthria This condition is characteristic of acute and chronic cerebellar lesions. It may be observed in multiple sclerosis and various degenerative disorders involving the cerebellum or its peduncles, or as a sequel of anoxic encephalopathy and rarely of heat stroke. The principal abnormalities are slowness of speech, slurring, monotony, and unnatural separation of the syllables of words (scanning). The coordination of speech and respiration is disordered. There may not be enough breath to utter certain words or syllables, and others are expressed with greater force than intended (explosive speech). Scanning dysarthria, speaking metronomically as if scanning poetry for meter (see page 77), is another cerebellar pattern distinctive and is due most often to mesencephalic lesions involving the brachium conjunctivum. However, in some cases of cerebellar disease, especially if there is an element of spastic weakness of the tongue from corticobulbar tract involvement, there may be only a slurring dysarthria, and it is not possible to predict the anatomy of the lesions from analysis of speech alone. Myoclonic jerks involving the speech musculature may be superimposed on cerebellar ataxia in a number of diseases.

Acquired Stuttering This abnormality, characterized by interruptions of the normal rhythm of speech by involuntary repetition and prolongation or arrest of uttered letters or syllables, is a common developmental disorder, discussed in Chap. 38. But as pointed out by Rosenbek et al. and by Helm and colleagues, it may appear in patients who are recovering from aphasic disorders and who had never stuttered in childhood. This acquired stuttering in adults resembles the developmental type in that the repetitions, prolongations, and blocks are restricted to the initial syllables of words, and there is no adaptation. However, it involves grammatical as well as substantive words and is generally unaccompanied by grimacing and associated movements. In many instances, acquired stuttering is transitory; if it is permanent, according to Helm and associates, bilateral cerebral lesions are present. Nevertheless we have observed some cases in which only a left-sided, predominantly motor aphasia provided the background for stuttering, and others in which stuttering was an early sign of cerebral glioma originating in the left parietal region. Benson also cites patients in whom stuttering accompanied fluent aphasia. Noteworthy is the fact that stuttering differs from palilalia, in which there is repetition of a word or phrase with increasing rapidity, and from echolalia, in which there is an obligate repetition of words or phrases. The causative lesion in acquired stuttering may be subcortical and even, as in an exceptional case described by Ciabarra and colleagues, located in the pons. The treatment of Parkinson disease with L-dopa and, occasionally, an acquired cerebral lesion may reactivate developmental stuttering. The latter may explain the emergence of stuttering with oddly situated lesions, such as the aforementioned pontine infarct.

Aphonia and Dysphonia

Finally, a few points should be made concerning the fourth group of speech disorders, i.e., those due to disturbances of phonation. In adolescence there may be a persistence of the unstable “change of voice” normally seen in boys during puberty. As though by habit, the patient speaks part of the time in falsetto, and the condition may persist into adult life. Its basis is unknown. Probably the larynx
is not masculinized, i.e., there is a failure in the spurt of growth (length) of the vocal cords that ordinarily occurs in pubertal boys. Voice training has been helpful.

Paresis of respiratory movements, as in myasthenia gravis, Guillain-Barré syndrome, and severe pulmonary disease, may affect the voice because insufficient air is provided for phonation. Also, disturbances in the rhythm of respiration may interfere with the fluency of speech. This is particularly noticeable in extrapyramidal diseases, where one may observe that the patient tries to talk during part of inspiration. Another common feature of the latter diseases is the reduction in volume of the voice (hypophonia) due to limited excursion of the breathing muscles; the patient is unable to shout or to speak above a whisper. Whispering speech is also a feature of advanced Parkinson disease, stupor, and occasionally concussive brain injury and frontal lobe lesions, but strong stimulation may make the voice audible.

With paresis of both vocal cords, the patient can speak only in whispers. Since the vocal cords normally separate during inspiration, their failure to do so when paralyzed may result in an inspiratory stridor. If one vocal cord is paralyzed—as a result of involvement of the tenth cranial nerve by tumor, for example—the voice becomes hoarse, low-pitched, rasping, and somewhat nasal in quality. The pronunciation of certain consonants such as b, p, n, and k is followed by an escape of air into the nasal passages. The abnormality is sometimes less pronounced in recumbency and increased when the head is thrown forward. Prolonged tracheal intubation that causes pressure necrosis of the posterior cricoarytenoid cartilage and the underlying posterior branch of the laryngeal nerve is an increasingly commoniatrogeniccause.

**Spasmodic (Spastic) Dysphonia** This is a relatively common condition about which little is known. *Spasmodyphonia* is a better term than spasmodic dysphonia, since the adjective *spastic* suggests corticospinal involvement, whereas the disorder is probably of extrapyramidal origin. The authors, like most neurologists, have seen many patients, middle-aged or elderly men and women, otherwise healthy, who lose the ability to speak quietly and fluently. Any attempt to speak results in simultaneous contraction of all the speech musculature, so that the patient’s voice is strained and speaking requires a great effort. The patient sounds as though he were trying to speak while being strangled. Shouting is easier than quiet speech, and whispering is unaltered. Other actions utilizing approximately the same muscles (swallowing and singing) are usually unimpaired.

Spasmodic dysphonia is usually nonprogressive and occurs as an isolated phenomenon, but we have observed exceptions in which it occurs in various combinations with blepharospasm, spasmodic torticollis, writer’s cramp, or some other type of segmental dystonia. The nature of spasmodic dysphonia is unclear. As a neurologic disorder, it is akin to writer’s cramp, i.e., a restricted dystonia (see Chap. 6). We have at times had great difficulty differentiating a severe essential tremor of voice from spasmodic dysphonia (fortunately, the treatments are similar).

**Treatment** Speech therapists, observing such a patient strain to achieve vocalization, often assume that relief can be obtained by making the patient relax, and psychotherapists believed at first that a search of the patient’s personal life around the time when the dysphonia began would enable the patient to understand the problem and regain a normal mode of speaking. But both these methods have failed without exception. Drugs useful in the treatment of Parkinson disease and other extrapyramidal diseases are practically never effective. Crushing of one recurrent laryngeal nerve can be beneficial, but recurrence is to be expected. The most effective treatment, comparable to treatment of other segmental dystonias, consists of the injection of 5 to 20 U of botulinum toxin, under laryngoscopic guidance, into each thyroarytenoid or cricothyroid muscle. Relief lasts for several months. An anatomic abnormality has not been demonstrated, but careful neuropsychologic studies have not been made.

Glottic spasm—as in tetanus, tetany, and certain hereditary metabolic diseases—results in crowing, stridorous phonation. Hoarseness and raspiness of the voice may also be due to structural changes in the vocal cords, the result of cigarette smoking, acute or chronic laryngitis, polyps, edema after extubation, etc.

SECTION 6

DISORDERS OF ENERGY, MOOD, AND AUTONOMIC AND ENDOCRINE FUNCTIONS
CHAPTER 24

FATIGUE, ASTHENIA, ANXIETY, AND DEPRESSIVE REACTIONS

In this chapter, we consider the clinically related phenomena of lassitude, fatigue, nervousness, irritability, anxiety, and depression. These complaints, though more abstruse than paralysis, sensory loss, seizures, or aphasia, are no less important, if for no other reason than their frequency in neurologic and general practice. In an audit of one neurologic outpatient department, anxiety and depressive reactions were the main preliminary diagnosis in 20 percent of the patients—second only to the symptom of headache (Digon et al). And in two primary care clinics in Boston and Houston, fatigue was the prominent complaint in 21 and 24 percent, respectively. Some of these symptoms, acting through the autonomic nervous system, represent only slight aberrations of function or only a heightening or exaggeration of normal reactions to all manner of medical and neurologic diseases; others are integral features of the diseases themselves; and still others represent subtle and inchoate disturbances of neuropsychiatric function, which are not yet sufficiently advanced to be readily identified as one of the diseases described in the section on psychiatry. It is because of their frequency and clinical significance that we have accorded them a chapter of their own among the cardinal manifestations of neurologic disease.

FATIGUE AND ASTHENIA

Of the symptoms to be considered in this chapter, lassitude and fatigue are the most frequent and often the most vague. 

Fatigue

refers to the universally familiar state of weariness or exhaustion resulting from physical or mental exertion. 

Lassitude

has much the same meaning, although more strictly it connotes an inability or disinclination to be active, physically or mentally. More than half of all patients entering a general hospital register a complaint of fatigability or admit to it when questioned. During World War I, fatigue was such a prominent symptom in combat personnel as to be given a separate place in medical nosology, namely combat fatigue, a term that came to be applied to practically all acute psychiatric disorders occurring on the battlefield. In subsequent wars it was a key element in the posttraumatic stress and Gulf War syndromes. In civilian life, fatigue is, of course, the central feature of the chronic fatigue syndrome. The common clinical antecedents and accompaniments of fatigue, its significance, and its physiologic and psychologic bases should, therefore, be matters of interest to all physicians. These aspects of the subject will be better understood if we first consider the effects of fatigue on the normal individual.

Effects of Fatigue on the Normal Person

Fatigue has both explicit and implicit effects, grouped under (1) a series of biochemical and physiologic changes in muscles and a reduced capacity to generate force—manifest as weakness, or asthenia; (2) an overt disorder in behavior, taking the form of a reduced output of work (work decrement) or a lack of endurance; and (3) a subjective feeling of tiredness and discomfort.

As to the biochemical and physiologic changes, continuous muscular work leads to depletion of muscle adenosine triphosphate (ATP), the supply of which is derived from creatine phosphate via phosphorylation of adenosine diphosphate (ADP). With continued and more intense exercise, a further supply of ATP becomes available as a result of the anaerobic breakdown of glycogen. When all the muscle glycogen has been consumed, exercise at a maximal level cannot be continued. However, mild to moderate exercise is still possible, since fatty acids provide an increasing share of muscle fuel. Gradually there is an accumulation of lactic acid and other metabolites, which in themselves reduce the power of muscular contraction and delay the recovery of muscle strength. Even in normal persons, extreme degrees of muscular effort, in which activity exceeds the provision of substrates, may result in necrosis of fibers and a rise in serum concentrations of creatine kinase (CK) (this effect is much more evident in individuals with one of the hereditary metabolic diseases of muscle described in Chap. 51).

The decreased productivity and capacity for work, which is a direct consequence of fatigue, has been investigated by industrial psychologists. Their findings clearly demonstrate the importance of motivational factors on work output, whether the work be of physical or mental type. More striking are individual constitutional differences in energy, which vary greatly, just as do differences in physique, intelligence, and temperament. It should be emphasized that in the majority of persons complaining of fatigue, one does not find true muscle weakness. This may be difficult to prove, for many such individuals are disinclined to exert full effort in tests of peak power of muscle contraction or in endurance of muscular activity. A disinclination to make an effort is also an essential characteristic of the fatigued mind.

The Clinical Significance of Lassitude and Fatigue

Patients experiencing lassitude and fatigue have a more or less characteristic way of expressing their symptoms. They say that they are “burned out,” “all done in,” “tired all the time,” “weary,” “exhausted,” or “pooped out”—or that they have “no pep,” “no ambition,” or “no interest.” They manifest their condition by showing an indifference to the tasks at hand, by talking much about how hard they are working and how stressed they are by circumstances; they are inclined to sit around or lie down or to occupy themselves with trivial tasks. On closer analysis, one observes that many such patients have difficulty in initiating activity and also in sustaining it—i.e., their endurance is diminished. This condition, of course, is the familiar aftermath of sleeplessness or prolonged mental or physical effort, and under such circumstances it is accepted as a normal physiologic reaction. When, however, similar symptoms...
appear without relation to such antecedents, they should be suspected of being the manifestations of disease.

The physician’s task is initially to determine whether the patient is merely suffering from the physical and mental effects of overwork without realizing it. Overworked, overwrought people are observable everywhere in our society. Their actions are both instructive and pitiful. Their behavior in this regard is said to be irrational in that they will not listen to reason; they seem to be impelled by certain notions of duty and refuse to think of themselves. In addition to fatigue, such persons frequently show irritability, restlessness, sleeplessness, and anxiety, sometimes to the point of panic attacks and a variety of somatic symptoms, particularly abdominal, thoracic, and cranial discomforts. Formerly, society accepted this state in responsible individuals and prescribed the obvious cure—a vacation. Even Charcot made time for regular “cures” during the year, in which he retired to a spa without family, colleagues, or the drain of work. Nowadays, the need to contain this type of stress, to which some individuals are more prone than others, has spawned a small industry of meditation, yoga, and similar “therapies.” Individuals with strong hobbies and athletic interests seem to be less subject to this problem.

A common error in diagnosis, however, is to ascribe fatigue to overwork when actually it is a manifestation of a neurosis or depression, as described below.

Lassitude and Fatigue as Symptoms of Psychiatric Illness

The great majority of patients who seek medical help for unexplained chronic fatigue and lassitude are found to have some type of psychiatric illness. Formerly this state was called “neurasthenia,” but since lassitude and fatigue rarely exist as isolated phenomena, the current practice is to label such cases according to the total clinical picture. The usual associated symptoms are nervousness, irritability, anxiety, depression, insomnia, headaches, dizziness, difficulty in concentrating, reduced sexual impulse, and loss (or sometimes increase) of appetite. In one series, 85 percent of persons admitted to a general hospital and seen in consultation by a psychiatrist for the chief complaint of chronic fatigue were diagnosed, finally, as having anxious depression or anxiety neurosis. In a subsequent study, Wessely and Powell found similarly that 72 percent of patients who presented to a neurologic center with unexplained chronic fatigue proved to have a psychiatric disorder, most often a depressive illness.

Several features are common to the psychiatric group with fatigue. Tests of peak muscle power on command, with the patient exerting full effort, reveal no weakness. The muscles retain their normal bulk and tendon reflex activity. The fatigue may be worse in the morning. There is an inclination to lie down and rest, but sleep does not follow. The fatigue is worsened by mild exertion and relates more to some activities than to others. Inquiry may disclose that the fatigue was first experienced in temporal relation to a grief reaction, a surgical operation, physical trauma such as an automobile accident, or a medical illness such as myocardial infarction. The feeling of fatigue interferes with mental as well as physical activities; the patient is easily worried, is mentally inactive, is “full of complaints,” and finds it difficult to concentrate in attempting to solve a problem or to read a book, or in carrying on a complicated conversation. Also, sleep is disturbed, with a tendency to early-morning waking, so that such persons are at their worst in the morning, both in spirit and in energy output. Their tendency is to improve as the day wears on, and they may even feel fairly normal by evening. It may be difficult to decide whether the fatigue is a primary manifestation of the disease or secondary to a lack of interest.

Among chronically fatigued individuals without medical disease, not all devote enough from normal to justify the diagnosis of neurosis or depression. Many persons, because of circumstances beyond their control, have little or no purpose in life and much idle time. They are bored with the monotony of their routine. Such circumstances are conducive to fatigue, just as the opposite, a strong emotion or a new enterprise that excites optimism and enthusiasm, will dispel fatigue. As mentioned, one must be aware of striking individual differences in energy potential. Some persons are born low in impulse and energy and become more so at times of stress; they have a lifelong inability to play games vigorously, to compete successfully, to work hard without exhaustion, to withstand illness or recover quickly from it, or to assume a dominant role in a social group—a “constitutional asthenia” (Kahn).

Fatigue with Medical Disease

Myopathic Fatigue  Not unexpectedly, fatigue and intolerance of exercise (i.e., fatigue with mild exertion) are prominent manifestations of myopathic disease, in which muscles are weak to begin with. Even in a disease such as myasthenia gravis, the muscles exhibiting fatigue are usually weak even in the resting state. The classes of myopathic disease in which weakness, inability to sustain effort, and excessive fatigue are notable features include the following: the muscular dystrophies, congenital myopathies, disorders of neuromuscular transmission (myasthenia gravis, Lambert-Eaton syndrome), toxic myopathies (e.g., due to cholesterol-lowering drugs), some of the glycogen storage myopathies, and mitochondrial myopathies. One type of glycogen storage disease—McArdle phosphorylase deficiency—is exceptional in that fatigue and weakness are accompanied by pain and sometimes by cramps and contracture. The first contractions after rest are of near normal strength, but after 20 to 30 contractions, there occurs a deep ache and an increasing firmness and shortening of the contracting muscles. The characteristics of these diseases are presented in the chapters on muscle disease. Another such process—acid maltase deficiency—is at times associated with disproportionate weakness and fatigue of respiratory muscles, which leads to dyspnea and retention of carbon dioxide.

Fatigue in Neurologic Diseases  Fatigue of varying degree is a regular feature of all diseases that are marked by denervation of muscle and loss of muscle fiber. Fatigue in these cases is due to the excessive work imposed on the intact muscle fibers (overwork fatigue). This is most characteristic of amyotrophic lateral sclerosis and the postpolio syndrome, but it also occurs in patients who are recovering from Guillain-Barré syndrome and in those with chronic polyneuropathy.

Not surprisingly, many neurologic diseases that are characterized by incessant muscular activity (Parkinson disease, double athetosis, Huntington disease, hemiballismus) induce fatigue. Also, muscles partially paralyzed by a stroke feel tired and may cause overall fatigue state (the distinguished neuroanatomist A. Brodal has given an interesting account of his own stroke and its effects on muscle power). Fatigue is often a major complaint of patients with multiple sclerosis; its cause is unknown, although the effect of interleukins circulating in the cerebrospinal fluid has been pos-
tulated. Also, the depression that follows stroke or myocardial infarction frequently presents with the complaint of fatigue rather than other signs of mood disorder. Inordinate fatigue is a common complaint among patients with postconcussive syndrome, or what we have termed posttraumatic nervous instability (page 764). Severe fatigue that causes the patient consistently to go to bed right after dinner and makes all mental activity effortful should suggest an associated depression. These central fatigue states and their possible mechanisms, almost all speculative, have been discussed by Chaudhuri and Behan.

Also, many states of disordered autonomic function in which static or orthostatic hypotension are features are commonly associated with a fatigue state. Whether there is in addition a central autonomic (hypothalamic) fatigue, aside from the endocrine changes discussed below, is uncertain, but such an entity seems plausible and has been included in models of the chronic fatigue illness.

**Systemic Diseases** A wide variety of medications and other therapeutic agents, particularly when first administered, commonly induce fatigue. The main offenders in this respect are antihypertensive drugs, especially beta-adrenergic blocking agents, anticonvulsants, antipsychotics, anxiolytics, chemotherapy and radiation therapy, and, paradoxically, many antidepressant and antipsychotic drugs. Introduction of these medications in gradually escalating doses may obviate the problem, but, just as often, an alternative medicine must be chosen. The administration of beta-interferon for the treatment of multiple sclerosis (and alpha-interferon for other diseases) induces fatigue of varying degree. Plasma exchange for the treatment of immune neuropathies and myasthenia gravis may be followed by fatigue for a day or so; this state should not be mistaken for a worsening of the underlying disease. Surgeons and nurses can testify to fatigue that comes with exposure to anesthetics in inadequately ventilated operating rooms. Similarly, fatigue and headache may result from exposure to carbon monoxide or natural gas in homes with furnaces in disrepair or from leaking gas pipes (but this is also a frequent delusion in anxious, depressed, or demented patients).

The sleep apnea syndrome is an important and often overlooked cause of fatigue and daytime drowsiness. In overweight men who snore loudly and need to nap frequently, testing for sleep apnea is indicated (page 344). Correcting the obstructive apnea that underlies this condition leads to a dramatic reduction in fatigue.

**Acute or chronic infection** is an important cause of fatigue. Everyone, of course, has at some time or other sensed the abrupt onset of exhaustion, a tired ache in the muscles, or an inexplicable listlessness, only to discover later that he was “coming down with the flu.” Chronic infections such as hepatitis, tuberculosis, brucellosis, infectious mononucleosis [Epstein-Barr virus (EBV) infection], subacute bacterial endocarditis, and perhaps the chronic effects of Lyme disease may not be evident immediately but should always be suspected when fatigue is a new symptom and disproportionate to other symptoms such as mood change, nervousness, and anxiety. More often, the fatigue begins with an obvious infection (such as influenza, hepatitis, or infectious mononucleosis) but persists for several weeks after the overt manifestations of infection have subsided; it may then be difficult to decide whether the fatigue represents the lingering effects of the infection or the infection has been complicated by psychologic symptoms during convalescence. This difficult problem is discussed below. Patients with systemic lupus, Sjögren syndrome, or polymyalgia rheumatica may complain of severe fatigue; in the last of these, fatigue may be the initial symptom.

**Metabolic and endocrine diseases** of various types may cause inordinate degrees of lassitude and fatigue. Sometimes there is, in addition, a true muscular weakness. In Addison and Simmonds diseases, fatigue may dominate the clinical picture. Aldosterone deficiency is another established cause of chronic fatigue. In persons with hypothyroidism with or without frank myxedema, lassitude and fatigue are frequent complaints, as are muscle aches and joint pains. Fatigue may also be present in patients with hypothyroidism, but it is usually less troublesome than nervousness. Uncontrolled diabetes mellitus is accompanied by excessive fatigability, as are hyperparathyroidism, hypogonadism, and Cushing disease.

Reduced cardiac output and diminished pulmonary reserve are important causes of breathlessness and fatigue, which are brought out by mild exertion. Anemia, when severe, is another cause, probably predicated on a similar inadequacy of oxygen supply to tissues. Mild grades of anemia are usually asymptomatic, and lassitude is far too often ascribed to it. An occult malignant tumor—e.g., pancreatic carcinoma—may announce itself by inordinate fatigue. In patients with metastatic carcinoma, leukemia, or multiple myeloma, fatigue is a prominent symptom. Uremia is accompanied by fatigue; the associated anemia may play a role. Any type of nutritional deficiency may, when severe, cause lassitude; in its early stages, this may be the chief complaint. Weight loss and a history of alcoholism and dietary inadequacy provide the clues to the nature of the illness.

For several weeks or months following myocardial infarction, some patients complain of fatigue out of all proportion to effort. In many of these patients, there is accompanying anxiety or depression. Much more difficult to understand is the complaint of fatigue that sometimes precedes myocardial infarction.

**Pregnancy** causes fatigue, which may be profound in the later months. To some extent the underlying causes, including the work of carrying excess weight and an anemia, are obvious; but if weight gain and hypertension are associated, pre-eclampsia should be suspected.

**Postviral and Chronic Fatigue Syndromes** A particularly difficult problem arises in the patient who complains of severe fatigue for many months or even years after a bout of infectious mononucleosis or some other viral illness. This has been appropriately called the postviral fatigue syndrome. The majority of patients are women between 20 and 40 years of age, but there are undoubtedly young men with the same illness. A few such patients were found to have unusually high titers of antibody to EBV, which suggested a causal relationship and gave rise to terms such as the chronic infectious mononucleosis or chronic EBV syndrome (Straus et al.). However, subsequent studies made it clear that a vast majority of patients with complaints of chronic fatigue have neither a clear-cut history of infectious mononucleosis nor serologic evidence of such an infection (Strauss; Holmes et al.). In some of these patients the fatigue state has allegedly been associated with obscure immunologic abnormalities similar to those attributed (spuriously) to silicone breast implants or minor trauma. The currently fashionable designation for these and other abstruse states of persistent fatigue is the chronic fatigue syndrome. Some perspective is provided by the recognition that a malady of this precise nature, under many different names, has long pervaded postindustrial western society, as described by Shorter in an informative history of the chronic
fatigue syndrome. The attribution of fatigue to viral infection and to ill-defined immune dysfunction are only the latest in a long line of putative explanations. At various times, even in our recent memory, colitis and other forms of bowel dysfunction, spinal irritation, hypoglycemia, brucellosis, and chronic candidiasis, “multiple chemical sensitivity,” or environmental allergies, among others, have been proposed as causes.

The current criteria for the diagnosis of chronic fatigue syndrome are the presence of persistent and disabling fatigue for at least 6 months, coupled with an arbitrary number (six or eight) of persistent or recurrent somatic and neuropsychiatric symptoms—including low-grade fever, cervical or axillary lymphadenopathy, myalgias, migrating arthralgias, sore throat, forgetfulness, headaches, difficulties in concentration and thinking, irritability, and sleep disturbances (Holmes et al).

A common association is with the similarly obscure entity and painful fibromyalgia state, consisting of neck, shoulder, and paraspinal pain and point tenderness (pages 190 and 1281). Despite these complaints, the patient may look surprisingly rested and robust and the neurologic examination is normal. The term myalgic encephalomyelitis, which is preferred in Great Britain, captures this association.

A number of such patients, in our experience, have complained of paresthesias in the feet or hands. On close questioning, many of these sensations prove to be odd, particularly numbness in the bones or muscles or fluctuating patches of numbness or paresthesias on the chest, face, or nose. Bizarre adjectives are sometimes given if the patient is allowed adequate time to describe the symptoms. A few of our patients have reported blurred or “close to” double vision. In neither case are there physical findings to corroborate the sensory experiences.

Complaints of muscle weakness are also frequent among such patients, but Lloyd and coworkers, who studied their neuromuscular performance and compared them with control subjects, found no difference in maximal isometric strength or endurance in repetitive submaximal exercise and no change in intramuscular acidosis, serum CK levels, or depletion of energy substrates. These individuals share with depressed patients a subnormal response to cortical magnetic motor stimulation after exercise (Samii et al), which can be said to match their symptoms of reduced endurance but otherwise is difficult to interpret. In a small number of affected persons, a chronic but usually mild hypotension, elicited mainly with tilting test and reversed by mineralocorticoids, has been proposed as a cause of chronic fatigue (Rowe et al). Electromyography and nerve conduction studies are invariably normal, as is the spinal fluid, but the electroencephalogram (EEG) may be mildly and nonspecifically slowed. Batteries of psychologic tests have disclosed variable impairments of cognitive function, misinterpreted by advocates of the “organic” nature of the syndrome as proof of some type of encephalopathy.

In a large group of patients who were studied 6 months after viral infections, Cope and colleagues found that none of the features of the original illness was predictive of the development of chronic fatigue; however, a previous history of fatigue or psychiatric morbidity and an indefinite diagnosis were often associated with persistent disability. In one study of more than 1000 patients who were observed for 6 months following an infective illness, the chronic fatigue syndrome was no more frequent than in the general population (Wessely et al). One thing is clear to the authors: that applying the label of chronic fatigue syndrome in susceptible individuals tends to always perpetuate this state.

Having oriented the above discussion to imply that many cases of chronic fatigue have a psychologic basis, we acknowledge that some previously healthy and nonneurotic individuals have become quite disabled for months or more after a severe febrile viral infection, the best characterized being mononucleosis, but undoubtedly other febrile illnesses are implicated as well. These cases, in our experience, have arisen suddenly in adolescents and young men who experience overwhelming fatigue during a well-documented and prolonged viral infection. They continue to take pleasure in activities in which they are able to participate, do not show anxiety or major depressive symptoms, and have the best prognosis, although complete recovery may take up to 3 to 5 years. Often these patients are able to define the date on which the illness began. The term postviral fatigue state is most appropriate for this group. Impressive in some of our cases have been severe headaches and orthostatic hypotension, with wide swings in blood pressure resulting in syncope as well as intermittent hypertension. Alcohol intolerance may develop. It would seem that the more ambiguous and less severe cases of chronic fatigue occurring in women, particularly those with fibromyalgia, have a different basis, but this cannot be stated with certainty.

At the present time, the status of the chronic fatigue syndrome is undecided. The possibility of an obscure metabolic or immunologic derangement secondary to a viral infection cannot be dismissed, as discussed by Swartz, but it seems unlikely in the majority of cases that lack such a history. Certainly, high levels of cytokines, such as occur after many types of illness and with cancer, and some of the numerous endocrine aberrations are capable of causing fatigue and lethargy. Treatment is discussed below.

**Differential Diagnosis of Fatigue**

If one looks critically at patients who seek medical help because of incapacitating exhaustion, lassitude, and fatigability (sometimes incorrectly called “weakness”), it is evident that the most commonly overlooked diagnoses are anxiety and depression. The correct conclusion can usually be reached by keeping these illnesses in mind as one elicits the history from patient and family. Difficulty arises when symptoms of the psychiatric illness are so inconspicuous as not to be appreciated; one comes then to suspect the diagnosis only by having eliminated the common medical causes. Repeated observation may bear out the existence of an anxiety state or gloomy mood, as the patient resists rehabilitation. Strong reassurance in combination with a therapeutic trial of antianxiety or antidepressant drugs may suppress symptoms of which the patient was barely aware, thus clarifying the diagnosis. The constitutionally asthenic individual, described earlier, is recognized by the characteristic lifelong behavioral pattern disclosed by his biography. The best that can be done is to assist the patient in adjusting to the adverse circumstances that have brought him under medical surveillance.

Tuberculosis, brucellosis, Lyme disease, hepatitis, subacute bacterial endocarditis, mycoplasmal pneumonia, EBV, cytomegalovirus (CMV), coxsackie B and other viral infections, and malaria, hookworm, giardiasis, and other parasitic infections need to be considered in the differential diagnosis and an inquiry made for their characteristic symptoms, signs, and, when appropriate, laboratory findings; such are infrequently found. There should also be a search for anemia, azotemia, chronic inflammatory disease such as temporal arteritis–polymyalgia rheumatica (sedimentation rate), and occult tumor; an endocrine survey (thyroid, calcium, and cortisol
levels) and an evaluation for cancer are also in order in obscure cases. It must be remembered that chronic intoxication with alcohol, barbiturates, or other sedative drugs, some of which are given to suppress nervousness or insomnia, may contribute to fatigability. The rapid and recent onset of fatigue should always suggest the presence of an infection, a disturbance in fluid balance, gastrointestinal bleeding, or rapidly developing circulatory failure of either peripheral or cardiac origin. The features that suggest sleep apnea have been mentioned above and are discussed further on page 344.

Finally, it bears repeating that lassitude and fatigue must always be distinguished from genuine weakness of muscle. The demonstration of reduced muscular power, reflex changes, fasciculations, and atrophy sets the case analysis along different lines, bringing up for particular consideration diseases of the peripheral nervous system or of the musculature Rare, difficult-to-diagnose diseases that cause inexplicable muscle weakness and exercise intolerance are masked hyperthyroidism, hyperparathyroidism, ossifying hemangiomata with hypophosphatemia, some of the kalemic periodic paralyses, hyperinsulinism, disorders of carbohydrate and lipid metabolism, the mitochondrial myopathies, and possibly adenylate deaminase deficiency.

**Treatment** It is our impression that most such patients who have not had a clear preceding febrile viral infection or one of the medical illnesses associated with fatigue from the outset are depressed. They are best treated with gradually increasing exercises and antidepressant medication, although this regimen is not always successful. There are reports of success in treating these patients with mineralocorticoids (predicated on the above-mentioned orthostatic intolerance), estradiol patches, hypnosis, and a variety of other medical and nonmedical treatments. Cognitive and behavioral therapies have the most consistent record of success. The numerous trials relating to treatment of chronic fatigue syndrome are carefully summarized in the Effective Health Care Report from the National Health Service Centre for Reviews and Dissemination, which comes to no firm conclusions. A very few patients exhibit the special psychologic disorder related to litigation (compensation neurosis). Noteworthy is the frequency with which a similar syndrome has become the basis of court action against employers, as in the “sick-building syndrome,” or claims against the government. Attribution to Lyme disease should be resisted without firm evidence of a clinical infection.

**NERVOUSNESS, ANXIETY, STRESS, AND IRRITABILITY**

The world is full of nervous, tense, apprehensive, and worried people. The stresses of contemporary society are often blamed for their plight. The poet W. H. Auden referred to his era as “the age of anxiety,” and little has changed since then. Medical historians have identified comparable periods of pervasive anxiety dating back to the time of Marcus Aurelius and Constantine, when societies were undergoing rapid and profound changes and individuals were assailed by an overwhelming sense of insecurity, personal insignificance, and fear of the future (Rosen).

Like lassitude and fatigue, nervousness, irritability, and anxiety are among the most frequent symptoms encountered in office and hospital practice. A British survey found that more than 40 percent of the population, at one time or another, experienced symptoms of severe anxiety, and about 5 percent suffered from lifelong anxiety states (Lader). The vast amounts of antianxiety drugs and alcohol that are consumed in our society would tend to corroborate these figures. Of course, some degree of nervousness and anxiety is experienced by any person facing a challenging or threatening task for which he may feel unprepared and inadequate. In such cases, anxiety is not abnormal, and the alertness and attention that accompany it may actually improve performance up to a point. In a similar vein, if worry or depression stands in clear relation to serious economic reverses or loss of a loved one, the symptom is usually accepted as normal. Only when it is excessively intense or prolonged or when accompanying visceral derangements are prominent do anxiety and depression become matters of medical concern. Admittedly, the line that separates normal emotional reactions and pathologic ones is not sharp. These matters are dealt with more fully in Chap. 56.

In this chapter we are concerned with nervousness, irritability, stress, anxiety, and depression as symptoms, together with currently accepted views of their origins and biologic significance.

**Anxiety Reactions and Panic Attacks**

There is no unanimity among psychiatrists as to whether symptoms of nervousness, irritability, anxiety, and fear comprise a single emotional reaction, varying only in its severity or duration, or a group of discrete reactions, each with distinctive clinical features. In some writings, anxiety is classified as a form of subacute or chronic fear. However, there is reason to question this assumption. Anxious patients, when frightened under experimental conditions, state that the fear reaction differs in being more overwhelming. The exceedingly frightened person is “frozen,” unable to act or to think clearly, and his responses are automatic and sometimes irrational. The fear reaction is characterized by overactivity of both the sympathetic and parasympathetic nervous systems, and the parasympathetic effects (bradycardia, sphincteric relaxation) may predominate—unlike anxiety, in which sympathetic effects are the more prominent. Long ago, Cicero distinguished between an acute and transient attack of fear provoked by a specific stimulus (angor) and a protracted state of fearfulness (anxietas). This distinction was elaborated by Freud, who regarded fear as an appropriate response to a sudden, unexpected external threat and anxiety as a neurotic maladjustment (see below).

Less readily distinguishable from anxiety is the complaint of nervousness. By this vague term the lay person usually refers to a state of restlessness, tension, uneasiness, apprehension, irritability, or hyperexcitability. Unfortunately, the term may have a wide range of other connotations as well, such as thoughts of suicide, fear of killing one’s child or spouse, a distressing hallucination or paranoid idea, a frankly hysterical outburst, or even tics or tremulousness. Obviously, a careful inquiry as to what the patient means in complaining of nervousness is always a necessary first step in the analysis of this complaint.

Most often nervousness represents no more than a transient psychic and behavioral state in which the person is maximally challenged or threatened by difficult personal problems. Some persons claim to have been nervous throughout life or to be nervous periodically for no apparent reason. In these instances the symptoms blend imperceptibly with those of anxiety or depression, described below.

We use the term anxiety to denote an intermittent or sustained emotional state characterized by subjective feelings of nervousness, irritability, uneasy anticipation, and apprehension, often but by no means always with a definite topical content and the physiologic
accompaniments of strong emotion, i.e., one or more of the symptoms of breathlessness, tightness in the chest, choking sensation, palpitation, increased muscular tension, giddiness, trembling, sweating, and flushing. By topical content is meant the idea, person, or object about which the person is anxious. The vasomotor and visceral accompaniments are mediated through the autonomic nervous system, particularly its sympathetic part, and involve also the thyroid and adrenal glands.

**Panic Attacks** The symptoms of anxiety may be manifest either in acute episodes, each lasting several minutes or up to an hour, or as a protracted state that may last for weeks, months, or years. In the panic attack, or panics, as they are called, the patient is suddenly overwhelmed by feelings of apprehension, or a fear that he may lose consciousness and die, have a heart attack or stroke, lose his reason or self-control, become insane, or commit some horrible crime. These experiences are accompanied by a series of physiologic reactions, mainly sympathoadrenal hyperactivity, resembling the “fight-or-flight” reaction. Breathlessness, a feeling of suffocation, dizziness, sweating, trembling, palpitation, and precordial or gastric distress are typical but not invariable physical accompaniments. As a persistent and less severe state, the patient experiences fluctuating degrees of nervousness, palpitation or excessive cardiac impulse, shortness of breath, light-headedness, faintness, easy fatigue, and intolerance of physical exertion.

Attacks tend to occur during periods of relative calm and in nonthreatening circumstances. Usually, the apprehension and physical symptoms escalate over a period of minutes to an hour and then abate over 20 to 30 min, leaving the patient tired and weak. The dramatic symptoms of the panic attack have usually abated by the time the patient reaches a doctor’s office or an emergency department, but the blood pressure may still be elevated and there may be tachycardia. Otherwise the patient looks remarkably collected. Often, discrete anxiety attacks and persistent states of anxiety merge with one another. The fear of further attacks leads many patients, particularly women, to become agoraphobic and homebound, fearing public places, especially if alone.

Because panic is a common disorder, affecting 1 to 2 percent of the population at some time in their lives, and the symptoms mimic neurologic disease, the neurologist is often called upon to distinguish panic attacks from temporal lobe seizures or from vertiginous diseases. Except for the occasional inability of the patient to think or articulate clearly during a panic, the manifestations of epilepsy are quite different. Practically never is consciousness lost during a panic attack. If dizziness predominates in the attacks, there may be concern about vertebrobasilar ischemia or labyrinthine dysfunction (see Chap. 15). Vertigo from any cause is accompanied by many of the autonomic symptoms displayed during a panic attack, but careful questioning in the latter will elicit the characteristic apprehension, breathlessness, and palpitations, and the absence of ataxia or other neurologic signs. It should be recognized that recurrent panic attacks and chronic anxiety have a familial aspect, with one-fifth of first-degree relatives affected and a high degree of concordance in monozygotic twins. The symptoms tend to be periodic, beginning in the patient’s twenties; a later onset is more obviously coupled with depression. Treatment of the depression with any one of a number of antidepressants (usually by trial and error) and the sparing use of anxiolytics are relatively successful in controlling panic disorders.

**Persistent Anxiety and Anxious Depression** Episodic or sustained anxiety without a disorder of mood (i.e., without depression) is properly classified as anxiety disorder or anxiety neurosis. The term neurocirculatory asthenia (among many others) has been applied to the chronic form with prominent fatigue and exercise intolerance (see also Chap. 56). The symptoms of anxiety may, however, be part of several other psychiatric disorders. Anxiety may be combined with other somatic symptoms in hysteria and is the most prominent feature of phobic neurosis. Symptoms of persistent anxiety with insomnia, lassitude, and fatigue should always raise the suspicion of a depressive illness, especially when they begin in middle adult life or beyond. Also, unexplained anxiety or panic attacks may sometimes herald the onset of a schizophrenic illness. As with fatigue, the symptoms of both anxiety and depression are prominent features of the syndrome of posttraumatic nervous instability (postconcussion syndrome), and of posttraumatic stress syndrome (see page 764). Also, when visceral symptoms predominate or the psychic counterparts of fear and apprehension are absent, the presence of thyrotoxicosis, Cushing disease, pheochromocytoma, hypoglycemia, and menopausal symptoms should be considered.

**Cause, Mechanism, and Biologic Significance of Nervousness and Anxiety**

These have been the subjects of much speculation, and completely satisfactory explanations are not available. As noted above, some individuals go through life in a chronic state of low-grade anxiety, the impetus for which may or may not be apparent. They are by nature, or constitutionally, nervous and subject to this character trait. Spontaneous episodes of anxiety demand another explanation. Some psychologists regard anxiety as anticipatory behavior, i.e., a state of uneasiness about something that may happen in the future. William McDougall spoke of it as “an emotional state arising when a continuing strong desire seems likely to miss its goal.” The primary emotion, somewhat muted perhaps, may be one of fear, and its arousal under conditions that are not overtly threatening may be explained as a conditioned response to some recondite component of a formerly threatening stimulus.

Physicians often feel inclined to search for evidence of visceral impairment, without success. The patient with anxiety neurosis is often in poor physical condition and has an increased blood lactate concentration in both the resting state and after exercise; infusions of lactic acid are said to make the symptoms of anxiety worse and, in susceptible individuals, to elicit a panic attack. The patient seems not to tolerate the work or exercise needed to build up his stamina. The urinary excretion of epinephrine has been found elevated in some patients; in others, there is an increased urinary excretion of norepinephrine and its metabolites. During periods of intense anxiety, aldosterone excretion is increased to two or three times normal.

There is also evidence that corticosteroids and corticotropin-releasing hormone (CRH) have a role in the genesis of anxiety. A systemic release of corticosteroid accompanies all states of stress, and the administration of corticosteroids may give rise to anxiety and panic in some patients and to depression in others—suggesting a linkage between steroid stimulation of the limbic system activities that generate these states. In animal models, stress elicited by predators or electric shock as well as by withdrawal of alcohol and other drugs precipitates activity in CRH pathways (amygdala to hypo-
The psychologic phenomenon of stress. Stress and Stress Syndromes causes a rapid decline in performance (Yerkes-Dodson law). Those lacking in anxiety. As anxiety increases, so does the standard anxious medical students performed better on examinations than those experiencing sporadic amounts of anxiety. Barratt and White found that mildly irritable behavior can be accounted for by one polymorphism of the serotonin transporter gene is provocative (Lesch et al) but requires further study. Anxiety, being so ubiquitous, is probably not without biologic significance. It strengthens social bonds at certain moments in life, such as parting with someone to whom we are emotionally attached. Anxiety may also impede the development of meaningful relationships, as it can lead to social withdrawal and avoidance. Anxiety is also a common symptom of depression, often accompanied by mood changes, such as sadness, loss of interest, or decreased energy. The phenomenon of irritable mood, or an irritable mood, must be familiar to almost everyone, exposed as we are to all of the noise, niggling inconveniences, and annoyances of daily life. The concept of irritable mood refers to a feeling of restlessness, irritability, or impatience, often accompanied by a desire for constant activity or movement. Irritability can be a response to environmental stressors, such as loud noises, overcrowding, or lack of privacy, or it can be a symptom of a medical condition, such as hyperthyroidism or hyperparathyroidism. Irritability in the workplace can be a sign of burnout or stress-related problems, and it can affect productivity and job satisfaction. The concept of irritable mood is often used interchangeably with the concept of irritable aggression, which refers to a state of irritability that is accompanied by a feeling of explosiveness and a desire to engage in aggressive behavior. Irritability and irritable aggression are common in certain medical conditions, such as hyperthyroidism or hyperparathyroidism, and in certain psychiatric disorders, such as bipolar disorder or acute stress disorder. Irritability and irritable aggression are also common in certain neurologic conditions, such as multiple sclerosis or traumatic brain injury. Irritability and irritable aggression can also be a result of medication side effects, such as those associated with blood pressure medication or antidepressants. The concept of irritable mood and irritable aggression is an important area of research, as it can help to identify individuals who are at risk for self-harm or violence and can guide the development of effective interventions.
DEPRESSIVE REACTIONS

There are few persons who do not at some time experience periods of discouragement and despair. As with nervousness, irritability, and anxiety, depression of mood that is appropriate to a given situation in life (e.g., grief reaction) is seldom the basis of medical concern. Persons in these situations tend to seek help only when their grief or unhappiness is persistent and beyond control. However, there are numerous instances in which the symptoms of depression assert themselves for reasons that are not apparent. Often the symptoms are interpreted as a medical illness, bringing the patient first to the internist or neurologist. Sometimes another disease is found (such as chronic hepatitis or other infection or post-infectious asthenia) in which chronic fatigue is confused with depression; more often the opposite pertains, i.e., an endogenous depression is the essential problem even when there has been evidence earlier of a viral or bacterial infection. Since the risk of suicide is not inconsiderable in the depressed patient, an error in diagnosis may be life-threatening.

From the patient and the family it is learned that the patient has been “feeling unwell,” “low in spirits,” “blue,” “glum,” “unhappy,” or “morbid.” There has been a change in his emotional reactions of which the patient may not be fully aware. Activities that he formerly found pleasurable are no longer so. Often, however, change in mood is less conspicuous than reduction in psychic and physical energy, and it is this type of case that is so often misdiagnosed by internists and neurologists. A complaint of fatigue is almost invariable; not uncommonly, it is worse in the morning after a night of restless sleep. The patient complains of a “loss of pep,” “weakness,” “tiredness,” “having no energy,” and/or that his job has become more difficult. His outlook is pessimistic. The patient is irritable and preoccupied with uncontrollable worry over trivialities. With excessive worry, the ability to think with accustomed efficiency is reduced; the patient complains that his mind is not functioning properly and he is forgetful and unable to concentrate. If the patient is naturally of suspicious nature, paranoid tendencies may assert themselves.

Particularly troublesome is the patient’s tendency to hypochondriasis. Indeed, most cases formerly diagnosed as hypochondriasis are now regarded as depression. Pain from whatever cause—a stiff joint, a toothache, fleeting chest or abdominal pains, muscle cramps, or other disturbances such as constipation, frequency of urination, insomnia, pruritus, burning tongue, weight loss—may lead to obsessive complaints. The patient passes from doctor to doctor seeking relief from symptoms that would not trouble the normal person, and no amount of reassurance relieves his state of mind. The anxiety and depressed mood of these persons may be obscured by their preoccupation with visceral functions.

When the patient is examined, his facial expression is often plaintive, troubled, pained, or anguished. The patient’s attitude and manner betray a prevailing mood of depression, hopelessness, and despondency. In other words, the affect, which is the outward expression of feeling, is consistent with the depressed mood. During the interview the patient may sigh frequently or be tearful and may cry openly. In some, there is a kind of immobility of the face that mimics parkinsonism, though others are restless and agitated (pausing, wringing their hands, etc.). Occasionally the patient will smile, but the smile impresses one as more a social gesture than a genuine expression of feeling.

The stream of speech is slow. Sighing is frequent. There may be long pauses between questions and answers. The latter are brief and may be monosyllabic. There is a paucity of ideas. The retardation extends to all topics of conversation and affects movement of the limbs as well (anergic depression). The most extreme forms of decreased motor activity, rarely seen in the office or clinic, border on muteness and stupor (“anergic depression”). Conversation is replete with pessimistic thoughts, fears, and expressions of unworthiness, inadequacy, inferiority, hopelessness, and sometimes guilt. In severe depressions, bizarre ideas and bodily delusions (“blood drying up,” “bowels are blocked with cement,” “I am half dead”) may be expressed.

Three theories have emerged concerning the cause of the pathologic depressive state: (1) that the endogenous form is hereditary, (2) that a biochemical abnormality results in a periodic depletion in the brain of serotonin and norepinephrine, and (3) that a basic fault in character development exists. These theories are elaborated in Chap. 57.

It is the authors’ belief that depressive states are among the most commonly overlooked diagnoses in clinical medicine. Part of the trouble is with the word itself, which implies being unhappy about something. *Endogenous depression should be suspected in all states of chronic ill health, hypochondriasis, disability that exceeds the manifest signs of a medical disease, neurasthenia and ongoing fatigue, chronic pain syndromes—all of which may be termed “masked depressions.” Inasmuch as recovery is the rule, suicide is a tragedy for which the medical profession must often share responsibility.

Depressive illnesses and theories of their causation and management are considered further in Chap. 57.

CHAPTER 25
THE LIMBIC LOBES AND THE NEUROLOGY OF EMOTION

The medical literature is replete with references to illnesses thought to be based on emotional disorders. Careful examination of clinical material discloses that a diversity of phenomena are being so classified: anxiety states, cycles of depression and mania, reactions to distressing life situations, so-called psychosomatic diseases, and illnesses of obscure nature. Obviously great license is being taken with the term emotional, the result no doubt of its indiscriminate nonmedical usage. Such ambiguity discourses neurologic analysis. Nevertheless, in certain clinical states, patients appear to be excessively apathetic or elated under conditions that are not normally conducive to such displays of emotion. It is to these disturbances that the following remarks pertain. First, however, one must be clear as to what is meant by “emotion.”

Emotion may be defined as any strong feeling state—e.g., fear, anger, excitement, love, or hate—associated with certain types of bodily changes (mainly visceral and under control of the autonomic nervous system) and leading usually to an impulse to action or to a certain type of behavior. If the emotion is intense, there may ensue a disturbance of intellectual functions—that is, a disorganization of rational thought and a tendency toward a more automatic behavior of unmodulated, stereotyped character.

In its most easily recognized human form, emotion is initiated by a stimulus (real or imagined), the perception of which involves recognition, memory, and specific associations. The emotional state that is engendered is mirrored in a psychic experience, i.e., a feeling, which is purely subjective and known to others only through the patient’s verbal expressions or by judging his behavioral reactions. This behavioral aspect, which is in part autonomous (hormonal-visceral) and in part somatic, shows itself in the patient’s facial expression, bodily attitude, vocalizations, or directed voluntary activity, an observable display for which we use the term affect. Subdivided, the components of emotion appear to consist of (1) the perception of a stimulus, which may be internal (an idea) or external, (2) the feeling, (3) the autonomic-visceral changes, (4) the outward display of affect, and (5) the impulse to a certain type of activity. In many cases of neurologic disease, however, it is not possible to separate these components from one another, and to emphasize one of them does no more than indicate the particular bias of the examiner. Obviously, neural networks of both affective response and cognition are involved.

Anatomic Relationships

The occurrence of abnormal emotional reactions in the course of disease is associated with lesions that preferentially involve certain parts of the nervous system. These structures have been grouped under the term limbic and are among the most complex and least understood parts of the nervous system. The Latin word limbus means “border” or “margin.” Credit for introducing the term limbic to neurology is usually given to Broca, who used it to describe the ring of gray matter (formed primarily by the cingulate and parahippocampal gyri) that encircles the corpus callosum and underlying upper brainstem. Actually, Thomas Willis had pictured this region of the brain and referred to it as the limbus in 1664. Broca preferred his term, le grand lobe limbique, to rhinencephalon, which was the term then in vogue and referred more specifically to structures having an olfactory function. Neuroanatomists who followed Broca affirmed his position and have extended the boundaries of the limbic lobe to include not only the cingulate and parahippocampal gyrus but also the underlying hippocampal formation, the subcallosal gyrus, and the paralimbic area. The terms visceral brain and limbic system, introduced by MacLean, have an even wider designation and more completely describe the structures involved in emotion and its expression; in addition to all parts of the limbic lobe, they include a number of associated subcortical nuclei such as those of the amygdaloid complex, septal region, preoptic area, hypothalamus, anterior thalamus, habenula, and central midbrain tegmentum, including the raphé nuclei and interpeduncular nucleus. The major structures comprised by the limbic system and their relationships are illustrated in Figs. 25-1 and 25-2.

The cytoarchitectonic arrangements of the limbic cortex clearly distinguish it from the surrounding neocortex (isocortex). The latter, as stated in Chap. 22, differentiates into a characteristic six-layered structure. In contrast, the inner part of the limbic cortex (hippocampus) is composed of irregularly arranged aggregates of nerve cells that tend to be in a trilaminar configuration (archi- or allocortex). The cortex of the cingulate gyrus, which forms the outer ring of the limbic lobe, is transitional between neocortex and allocortex—hence it is known as the mesocortex, or juxtallocortex. Information from a wide array of cortical neurons is funneled into the dentate gyrus and then to the CA (cornu ammonis) pyramidal cells of the hippocampus; output from the hippocampal formation is mainly from the pyramidal cells of the CA1 segment and subiculum. The amygdaloid complex, a subcortical nuclear component of the limbic system, also has a unique composition, consisting of several separable nuclei, each with special connections to other limbic structures.

The connections between the orbitofrontal neocortex and limbic lobes, between the individual components of the limbic lobes, and between the limbic lobes and the hypothalamus and midbrain reflect their many functional relationships in regard to emotion. At the core of this system lies the medial forebrain bundle, a complex set of ascending and descending fibers that connect the orbitomesiofrontal cortex, septal nuclei, amygdala, and hippocampus rostrally and certain nuclei in the midbrain and pons caudally. This system, of which the hypothalamus is the central part, was designated by Nauta as the septohypothalamomesencephalic continuum.

There are many other interrelationships between various parts of the limbic system, only a few of which can be indicated here. The best-known of these is the so-called Papez circuit. It leads from the hippocampus, via the fornix, to the mammillary body and septal and preoptic regions (Fig. 25-1). The bundle of Vicq d’Azyr (mamillothalamic tract) connects the mammillary nuclei with the anterior nuclei of the thalamus, which, in turn, project to the cingulate gyrus and then, via the cingulum, to the hippocampus. The cingulum runs concentric to the curvature of the corpus callosum;
it connects various parts of the limbic lobe to one another and projects to the striatum and to certain brainstem nuclei as well. Also, the cingulum receives fibers from the inferior parietal lobule and temporal lobe, which are multimodal suprasensory centers for the integration of visual, auditory, and tactile perceptions. It is connected to the opposite cingulum through the corpus callosum.

**Physiology of the Limbic System**

The functional properties of the limbic structures first became known during the third and fourth decades of the twentieth century. From ablation and stimulation studies, Cannon, Bard, and others established the fact that the hypothalamus contains the suprasegmental integrations of the autonomic nervous system, both the sympathetic and parasympathetic parts. Soon after, anatomists found different pathways from the hypothalamus to the neural structures subserving parasympathetic and sympathetic reflexes. One such segmental reflex, involving the sympathetic innervation of the adrenal gland, served as the basis of Cannon’s emergency theory of sympathoadrenal action, which for many years dominated thinking about the neurophysiology of acute emotion (see page 458).

Following Cannon, Bard localized the central regulatory apparatus for respiration, wakefulness, and sexual activity incorrectly, in the hypothalamus. Later, the hypothalamus was also found to contain neurosecretory cells, which control the secretion of the pituitary hormones; within it also are special sensory receptors for the regulation of hunger, thirst, body temperature, and levels of circulating electrolytes. Gradually the idea emerged of a hypothalamic-pituitary-autonomic system that is essential to both the basic homeostatic and emergency (“fight-or-flight”) reactions of the organism. The functional anatomy of these autonomic and neuroendocrine systems is discussed in Chaps. 26 and 27.

The impression of the great psychologists of the nineteenth century—that autonomic reactions were the essential motor component of instinctual feeling—has been corroborated. In fact, for a time, it was proposed that emotional experience was merely the self-awareness of these visceral activities (the James-Lange theory of emotion). The fallacy of this theory became evident when it was demonstrated by Cannon that the capacity to manifest emotional changes remained after all visceral affective fibers had been interrupted.

Although the natural stimuli for emotion involve the same neocortical perceptive-cognitive mechanisms as does nonemotional sensory experience, there are important differences, which relate to the prominent visceral effects and particular behavioral reactions evoked by emotion. Clearly, specific parts of the nervous system must be utilized. Bard, in 1928, first produced “sham rage” in cats by removing the cerebral hemispheres and leaving the hypothalamus and brainstem intact. This is a state in which the animal reacts to all stimuli with expressions of intense anger and signs of autonomic overactivity. In subsequent studies, Bard and Mountcastle found that only if the ablations included the amygdaloid nuclei on both sides would sham rage be produced; removal of all the neocortex but sparing of the limbic structures resulted in placidity. Interestingly, in the macaque monkey, a normally aggressive and recalcitrant animal, removal of the amygdaloid nuclei bilaterally greatly reduced the reactivities of fear and anger (see further on). The role of the hypothalamus and amygdala in the production of both directed and undirected anger and displays of rage has turned out to be far more complex. In any case, Papez, on the basis of these and his own anatomic observations, postulated that the limbic parts of the brain elaborate the functions of central emotion and participate as well in emotional...

![Figure 25-1](image-url)
expression. The intermediate position of the limbic structures enables them to transmit neocortical effects from their outer side to the hypothalamus and midbrain on their inner side.

The role of the cingulate gyrus in the behavior of animals and humans has been the subject of much discussion. Stimulation is said to produce autonomic effects similar to the vegetative correlates of emotion (increase in heart rate and blood pressure, dilatation of pupils, piloerection, respiratory arrest, breath-holding). More complex responses such as fear, anxiety, or pleasure have been reported during neurosurgical stimulative and ablative procedures, although these results are inconsistent. Bilateral cingulec- tomies performed in psychotic and neurotic patients result in an overall diminution of emotional reactions (Ballantine et al; Brown). Some investigators believe that the cingulate gyri are also involved in memory processing (functioning presumably in connection with the mediodorsal thalamic nuclei and mediotemporal lobes) and in exploratory behavior and visually focused attention. In humans, this system appears to be more efficient in the nondominant hemisphere, according to Bear. Baleydier and Mauguire emphasize this dual function—in cognition and in emotional reactions—of the cingulate gyrus.

Another aspect of limbic function has come to light as information is being acquired about neurotransmitters. The concentration of norepinephrine is highest in the hypothalamus and next highest in the medial parts of the limbic system; at least 70 percent of this monoamine is concentrated in terminals of axons that arise in the medulla and in the locus ceruleus of the rostral pons. Axons of other ascending fibers—especially those originating in the reticular formation of the midbrain and terminating in the amygdala and septal nuclei as well as in lateral parts of the limbic lobe—are rich in serotonin. The axons of neurons in the ventral tegmental parts of the midbrain, which ascend in the medial forebrain bundle and the nigrostriatal pathway, contain a high content of dopamine.

Perhaps this explains the observation that a severe depressive reaction may be produced by electrical stimulation of the substantia nigra with an aberrantly placed electrode for the treatment of Parkinson disease (see Chap. 39). Of unknown significance is the fact that the zinc content of the limbic system is the highest of any part of the nervous system.

All of this having been said, it would be a mistake to assume that the many structures listed above and their connections constitute a unified functional system. The term limbic system is a simplification, particularly since the various parts differ widely in respect to their connections with the neocortex and central nuclei, their transmitters, and their effects when damaged. But it can be said that lesions in this system most consistently and specifically alter emotionality; it therefore remains a useful concept.

**EMOTIONAL DISTURBANCES DUE TO DISEASES INVOLVING LIMBIC STRUCTURES**

Many of the foregoing ideas about the role of the limbic system have come from experimentation in laboratory animals. Only in relatively recent years have neurologists, primed with the knowledge of these studies, begun to relate emotional disturbances in patients with disease of limbic structures. These clinical observations, summarized in the following pages, are beginning to form an interesting chapter in neurology. The most readily recognized disturbances of emotion are listed in Table 25-1. The list is tentative, since our understanding of many of these states, particularly their pathologic basis, is incomplete. Only a small number of these derangements can be used as pathognomonic indicators of lesions and diseases in particular parts of the human brain. Panksepp thinks of emotional disturbances and their expression as reflective only of “spheres of influence” of certain brain mechanisms. We have found that, taken in context, these disturbances are useful diagnostically. And, as knowledge of emotional disorders increases, an understanding of the functioning of limbic structures will undoubtedly bring together large segments of psychiatry and neurology.

**Emotional Disturbances in Hallucinating and Deluded Patients**

These are best portrayed by the patient with a florid delirium. Threatened by imaginary figures and voices that seem real and
inexplicable, the patient trembles, struggles to escape, and displays the full picture of terror. The patient’s affect, emotional reaction, and visceral and somatic motor responses are altogether appropriate to the content of the hallucinations. We have seen a patient slash his wrists and another try to drown himself in response to hallucinatory voices that admonished them for their worthlessness and the shame they had brought on their families. But the abnormality in these circumstances is one of disordered perception and thinking, and we have no reason to believe that there is a derangement of the mechanisms for emotional expression.

There also occurs a state—difficult to classify—of overwhelming emotionality in patients who are in severe acute pain. The patient’s attention can be captured only briefly, but within moments there is a return to an extreme state of angst, groaning, and anger. We have encountered this with spinal subdural hemorrhage, subarachnoid hemorrhage, explosive migraine, trauma with multiple fractures, and intense pelvic, renal, or abdominal pain, all understandable as responses to extralimbic stimuli.

**Disinhibition of Emotional Expression**

**Emotional Lability**  It is a commonplace clinical experience that cerebral diseases of many types, seemingly without respect to location, weaken the mechanism of control of emotional expression—a mechanism that has been acquired over years of maturation. The degree to which this pertains varies with gender and ethnicity and has more to do with social norms than with biology. In certain cultures, women are permitted to cry in public but men are not.

In the realm of neurologic disease, a patient whose cerebrum has been damaged—for example, by a series of vascular lesions—may suffer the humiliation of crying in public upon meeting an old friend or hearing the national anthem, or of displaying uncontrollable laughter in response to a mildly amusing remark or an attempt to tell a funny story. There may also be easy vacillation from one state to another, an emotional lability that has for more than a century been accepted as a sign of “organic brain disease.” In this type of emotional disturbance, the response, while excessive, does not reach the degree of forced emotionality of the special form of lability described as pseudobulbar (see below); furthermore, it is inappropriate to the stimulus and the affect is congruent with the visceral and motor components of the expression. The anatomic substrate is obscure. Perhaps lesions of the frontal lobes more than those of other parts of the brain are conducive to this state, but the authors are unaware of a critical clinicoanatomic study that substantiates this impression. Emotional lability is a frequent accompaniment of diffuse cerebral diseases such as Alzheimer disease, but these diseases, of course, also involve the limbic cortex. Also under this heading might be included the tearfulness and facile mood that so often accompany chronic diseases of the nervous system, and the shallow facetiousness (Witzelsucht) and behavioral disinhibition of the patient with frontal lobe disease.

**Pathologic (Pseudobulbar, Forced, Spasmodic) Laughing and Crying**  This form of disordered emotional expression, characterized by outbursts of involuntary, uncontrollable, and stereotyped laughing or crying, has been well recognized since the late nineteenth century. Numerous references to these conditions (the Zwangsachen and Zwangsweinen of German neurologists and the rire et pleurer spasmodiques of the French) can be found in the writings of Oppenheim, von Monakow, and Wilson (see Wilson for historical references). The term emotional incontinence applied by psychiatrists is perhaps accurate but a bit pejorative. Forced laughing and crying always has a pathologic basis in the brain, either diffuse or focal; hence this stands as a syndrome of multiple causes. It may occur with degenerative and vascular diseases of the brain (Table 25-2) and no doubt is the direct result of them, but often the diffuse nature of the underlying disease precludes useful topographic analysis and clinicoanatomic correlation.

The best examples of pathologic laughing and crying are provided by lacunar vascular disease but also by amyotrophic lateral sclerosis, multiple sclerosis, and progressive supranuclear palsy, in each case the lesions being distributed bilaterally and generally involving the motor tracts, more specifically, the corticobulbar motor system, as discussed further on. They may also be part of the residue of the more widespread lesions of hypoxic-hypotensive encephalopathy,Binswanger ischemic encephalopathy, cerebral trauma, or encephalitis. Typical in our experience is a sudden hemiplegia from a stroke that is engrained upon a pre-existent (and often clinically silent) lesion in the opposite hemisphere; this sets the stage for the pathologic emotionality.

In this state there is often a striking incongruity between the loss of voluntary movements of muscles innervated by the motor nuclei of the lower pons and medulla (inability to forcefully close the eyes, elevate and retract the corners of the mouth, open and close the mouth, chew, swallow, phonate, articulate, and move the tongue) and the preservation of movement of the same muscles in yawning, coughing, throat clearing, and spasmodic laughing or crying (i.e., in reflexive pontomedullary activities). This is the motor syndrome of pseudobulbar palsy (page 427) for which reason the term pseudobulbar affective state has been applied to the emotional disorder.

In such cases, on the slightest provocation and sometimes for no apparent reason, the patient is thrown into a stereotyped spasm of laughter that may last for many minutes, to the point of exhaustion. Or, far more often, the opposite happens—the mere mention of the patient’s family or the sight of the doctor provokes an uncontrollable spasm of crying or, more accurately stated, a caricature of crying. The severity of the emotional incontinence or the ease with which it is provoked does not always correspond with the severity of the pseudobulbar paralysis or with an exaggeration of the facial and masseter ("jaw jerk") tendon reflexes. In some patients with forced crying and laughing, there is little or no detectable weakness of facial and bulbar muscles; in others, forced laughing and crying are lacking despite a severe upper motor neuron weakness of these muscles. In certain diseases, such as progressive

Pontine myelinolysis  
Wilson disease
supranuclear palsy and central pontine myelinolysis, of which pseudobulbar palsy is a frequent manifestation, forced laughing and crying are less dramatic or, in many cases, absent. Therefore the pathologic emotional state cannot be equated with pseudobulbar palsy even though the two usually occur together.

Is this pathologic state, whether one of involuntary laughing or of crying, activated by an appropriate stimulus? In other words, does the emotional response accurately reflect the patient’s affect or feeling? There are no simple answers to these questions. One problem, of course, is to determine what constitutes an appropriate stimulus for the patient in question. Virtually always, the emotional response is set off by some stimulus or thought; but usually it is trifling, or at least it appears so to the physician. Merely addressing the patient or making some casual remark in his presence may suffice. Certainly the emotional response is out of all proportion to the stimulus. Oppenheim and others stated that these patients need not feel sad when crying or mirthful when laughing, and at least in some cases this is in agreement with our experience. Other patients, however, do report a congruence of affect and emotional experience.

Noteworthy also are the stereotyped nature of the initial motor facial response and the relatively undifferentiated nature of the emotional reaction. Laughter or crying, as each proceeds, may merge, one with the other. Poeck puts great emphasis on the latter point, but it does not seem surprising when one considers the closeness of these two forms of emotional expression—a feature that is particularly evident in young children. Normal persons may cry when overjoyed and smile when sad. More impressive to us is the fact that in some patients with pseudobulbar palsy, laughing and crying, or caricatures thereof, are the only available forms of emotional expression; intermediate phenomena, such as smiling and frowning, are lost. In other patients with pseudobulbar palsy, it seems to us, there are lesser degrees of forced laughing and crying, perhaps bridging the gap between this phenomenon and the type of emotional lability discussed earlier.

Wilson, in his discussion of the anatomic basis and mechanism of forced laughing and crying, pointed out that both involve the same facial, vocal, and respiratory musculature and have similar visceral accompaniments (dilatation of facial vessels, secretion of tears, etc.). Two major supranuclear pathways control the ponto-medullary mechanisms of facial and other movements required in laughing and crying. One is the familiar corticobulbar pathway that runs from the motor cortex through the posterior limb of the internal capsule and controls volitional movements; the other is a more anterior pathway which descends just rostral to the knee of the internal capsule and contains facilitatory and inhibitory fibers. Unilateral involvement of the anterior pathway leaves the opposite side of the face under volitional control but paretic during laughing, smiling, and crying (emotional facial paralysis); the opposite is observed with a unilateral lesion of the posterior pathway. Wilson’s argument, based to some extent on clinicopathologic evidence, was that in pseudobulbar palsy it was the descending motor pathways, which normally inhibit the expression of the emotions, that were interrupted, although he was uncertain of the exact level. Almost 40 years later, Poeck, after reviewing all the published pathologic anatomy in 30 verified cases, was able to do more than conclude that supranuclear motor pathways are always involved, with loss of a control mechanism somewhere in the brainstem between thalamus and medulla. However, this clinical state is observed in amyotrophic lateral sclerosis, where the corticobulbar tracts may be involved at a cortical and subcortical level. As mentioned earlier, the lesions are bilateral in practically all instances (see Poeck in the References). There are, however, reports of spasmodic laughter lasting a month or two, following unilateral striatocapsular infarction (Cecchaldi et al), and occasional cases after unilateral pontine infarction or arteriovenous malformation, but these cases have not been verified pathologically.

Of interest is the beneficial effect on distressing pseudobulbar displays of drugs such as imipramine and fluoxetine (Schiﬀer et al). A study has also shown beneﬁt from dextromethorphan combined with quinidine in the pseudobulbar state of ALS (Brooks et al). In a number of personally observed cases, both the emotional lability and pathologic laughter and crying were partially suppressed by these drugs; in others there was no effect. Several small series have demonstrated a reduction in the intensity of both forced crying and laughter with the use of antidepressant drugs in the majority of patients.

A rare but probably related syndrome is le fou rire prodromique (prodromal laughing madness) of Péré, in which uncontrol- lable laughter begins abruptly and is followed after several hours by hemiplegia. We have seen two such cases in which basilar artery occlusion evolved after a brief bout of such forced laughter. Martin cites examples where patients laughed themselves to death. Again, the pathologic anatomy is unsettled. Protracted laughing and (less often) crying may occur also as a manifestation of epileptic sei- zures, usually of psychomotor type. Ictal laughter is usually without affect. Daly and Mulder referred to these as “gelastic” seizures. The concurrence of gelastic seizures and precocious puberty is highly characteristic of an underlying hamartoma (or other lesion) of the hypothalamus (see Chaps. 16 and 27).

Aggressiveness, Anger, Rage, and Violence

Aggressiveness is an integral part of social behavior. The emergence of this trait early in life enables the individual to secure a position in the family and later in an ever-widening social circle. Individual differences, probably inherited, are noteworthy. Timidity, for example, is a persistent trait, recognized in infancy (Kagan). Males tend to be more aggressive than females. The degree to which excessively aggressive behavior is tolerated varies in different cultures. In most civilized societies, tantrums, rage reactions, and outbursts of violence and destructiveness are not condoned, and one of the principal objectives of training and education is the suppression and sublimation of such behavior. The rate at which such developmental process proceeds varies from one individual to another. In some, especially males and the mentally backward, it is not complete until 25 to 30 years of age; until that time, the deviant behavior is called sociopathy (see Chap. 28). Undoubtedly, from our own casual and others more systematic observations, this is in part an inherited tendency.

That seemingly groundless outbreaks of unbridled but disor- ganized rage may rarely represent the initial or main manifestation of disease is not fully appreciated. A patient with these symptoms may, with little provocation, change from a reasonable state to one of the wildest rage, with a blindly furious impulse to violence and destruction. In such states the patient appears out of contact with reality and is impervious to all argument or pleading. As far as one can tell, this pattern of behavior is associated with a feeling of anger. What is so obviously abnormal is the provocation of the attack by some trifling event and a degree of violence that is out of all proportion to the stimulus. There are examples also of a dissociation of affect and behavior in which the patient may spit, cry out, attack, or bite without seeming to be angry. This is especially true of the mentally retarded.
Although the functional anatomy of these states of anger, rage, and aggressiveness has not been fully established, all the human and animal data point to an origin in the temporal lobes and particularly in the amygdala. In humans, stimulation of the medial amygdaloid nuclei, through deep electrodes, evokes a display of anger, whereas stimulation of the lateral nuclei does not; destruction of the amygdaloid complex bilaterally reportedly reduces aggressiveness (Kiloh; Narabayashi et al.). (Lesions in the mediodorsal thalamic nuclei, which receive projections from the amygdaloid nuclei, render humans more placid and docile.) In an unintended experiment in a patient with Parkinson disease, Bejani and colleagues found that aggressive behavior could be induced by stimulation of the postero medial hypothalamus. As with the comparable elicitation of depression from an aberrant electrode in the substantia nigra that was reported by the same group, it is not clear whether the effect was due to changes in adjacent neuronal pathways or whether the physiologic response was excitatory or the result of inhibition of neuronal activity.

Sex hormones influence the activity of these temporal lobe circuits; testosterone promotes aggressiveness and estradiol suppresses it, suggesting an explanation for sex differences in the disposition to anger. Surprisingly, propranolol and lithium have benefited such patients more than haloperidol, the phenothiazine drugs, or sedatives.

Observations in experimental animals have corroborated the observations in humans. As mentioned earlier, bilateral removal of the amygdaloid nuclei in the macaque greatly reduces the reactions of fear and anger. Electrical stimulation in or near the amygdala of the unanesthetized cat yields a variety of motor and vegetative responses. One of these has been referred to as the fear or flight response, in which the animal appears frightened and runs away and hides; another is the anger or defense reaction, characterized by growling, hissing, and piloerection. However, structures other than the amygdaloid nuclei are also involved in these reactions. Lesions in the ventromedial nuclei of the hypothalamus (which receive an abundant projection of fibers from the amygdaloid nuclei via the stria medullaris and possibly the ventral amygdala—fugal pathway) have been shown to cause aggressive behavior, and bilateral ablation of Brodmann area 24 (rostral cingulate gyrus) has produced the opposite state—tameness and reduced aggressiveness, at least in some species.

Rage reactions of the density described above may be encountered in the following medical settings: (1) rarely as part of a temporal lobe seizure; (2) as an episodic reaction without recognizable seizures or other neurologic abnormality, as in certain sociopaths; (3) in the course of a recognizable acute neurologic disease; or (4) with the clouding of consciousness that accompanies a metabolic or toxic encephalopathy. Each of these circumstances is considered below.

Rage in Temporal Lobe Seizures (See also page 277) According to Gastaut and colleagues, a directed attack of uncontrollable rage may occur either as part of a seizure or as an interictal phenomenon. Some patients describe a gradual heightening of excitability for 2 to 3 days, either before or after a seizure, before bursting into a rage. Certainly such attacks have been observed, but they are very rare. However, a lesser degree of aggressive behavior as part of a temporal lobe seizure is not uncommon; it is usually part of the ictal or postictal behavioral automatism and tends to be brief in duration and poorly directed. Usually the lesion is in the temporal lobe of the dominant hemisphere. Similarly, a feeling of rage or severe anger occurs but is relatively infrequent as an ictal emotion—much less common than feelings of fear, sadness, or pleasure (Williams reported only 17 cases of anger among 165 patients with ictal emotion). Geschwind has emphasized the frequency of a profound deepening of all of the patient’s emotional experiences in temporal lobe epilepsy.

Rage Attacks without Apparent Seizure Activity In some instances of this type, the patient had from early life been hot-headed, intolerant of frustration, and impulsive, exhibiting behavior that would be classed as sociopathic (Chap. 56). There are others, however, who, at certain periods of life, usually adolescence or early adulthood, begin to have episodes of wild, aggressive behavior. Alcohol or some other drug may set them off. One suspects epilepsy, but there is no history of a recognizable seizure and no interruption of consciousness, which is so typical of complex partial epilepsy. We have been consulted from time to time by patients (men and suprisingly, also women) who report a proclivity to anger, cursing, and momentary unreasonableness in behavior that is acquired in adulthood; the question was of seizures as the cause. Usually such individuals are remorseful afterwards and otherwise function at a high cognitive level, but others have been sociopaths. The electroencephalogram (EEG) is either normal or nonspecifically abnormal. This seems to be an inherited trait. In a very few such cases, in which aggression has resulted in serious injury to others (or homicide), depth electrodes placed in the amygdaloid nuclear complex have recorded what could be construed as seizure discharges. Attacks of excitement and various autonomic accompaniments have been aroused by stimulation of the same region, and the abnormal behavior has in some instances been relieved by ablation of the abnormally discharging structures. Mark and Ervin have documented a number of examples of this “dyscontrol syndrome,” but we are doubtful that they are truly epileptic.

Violent Behavior in Acute or Chronic Neurologic Disease From time to time one encounters patients in whom intense excitement, rage, and aggressiveness begin abruptly in association with an acute neurologic disease or in a phase of partial recovery. In most cases the medial and anterior temporal lobes are implicated. Cranial trauma is the most frequent cause of what has been called “organic personality disorder of the explosive type.” Serious head injury with protracted coma may be followed by personality changes consisting of aggressive outbursts, suspiciousness, poor judgment, indifference to the feelings of family, and variable degrees of cognitive impairment. Hemorrhagic leukoencephalitis, lobar hemorrhage, infarction, and herpes simplex encephalitis affecting the medio-orbital portions of the frontal lobes and anterior portions of the temporal lobes may have the same effect (Fig. 25-3). Fisher has noted the occurrence of intense rage reactions as an aftermath of a dominant temporal lobe lesion that had caused a Wernicke type of aphasia. Cases of this type have also been reported with ruptured aneurysm of the circle of Willis and extension of a pituitary adenoma; references to these reports can be found in the articles of Poeck (1969) and of Pilieri.

Also of interest in this connection are the effects of slow-growing tumors of the temporal lobe. Malamud described outbursts of rage in association with temporal lobe gliomas. Other patients harboring such tumors had no rage reactions but exhibited a clinical picture superficially resembling schizophrenia. It is noteworthy that 8 of the 9 patients with temporal lobe glioma described by Malamud also had seizures. Several similar examples have been reported (see Poeck for references). The anteromedial part of the left temporal lobe has been the site of the tumor
in the majority of cases. Falconer and Serafinetinides have described patients with rage reactions in whom there was a hamartoma or sclerotic focus in this region. However, the precise anatomy has not been demarcated.

**Aggressive Behavior in Acute Toxic-Metabolic Encephalopathies** Here the patient is not in a clear-headed state and rage or aggression is superimposed on an encephalopathy of toxic or metabolic origin. The most dramatic examples in our experience have been associated with hypoglycemic reactions. When the patient is left alone, the aggressive behavior is undirected and disorganized, but anyone in the immediate neighborhood may be struck by flailing limbs. In medical writings, this type of activity is described as “bizarre behavior” but is rarely characterized further. Such patients are clearly out of contact. Their attention cannot be gained for a moment, and attempts at physical restraint provoke an even more violent reaction.

A similar state may occur with phencyclidine and cocaine intoxication and at times with other hallucinogens, always with agitation and usually hallucinosis. Outbursts of rage and violence with alcohol intoxication are somewhat different in nature: some instances represent a rare paradoxical or idiosyncratic reaction to alcohol (“pathologic intoxication,” see page 1006); in other cases, alcohol appears to disinhibit an underlying sociopathic behavior pattern.

**Placidity and Apathy**

The animal organism normally indulges in and displays highly energized, exploratory activity of its environment. Some of this activity is motivated by the drive for sexual satisfaction and procurement of food; in humans, it may be a matter of curiosity. According to Panksepp and others, these activities are governed by “expectancy circuits,” involving nuclear groups in mesolimbic and mesocortical dopaminergic circuits connected with the diencephalon and mesencephalon via the medial forebrain bundles; lesions that interrupt these connections are said to abolish the expectancy reactions. Positron emission tomography (PET) studies correlate functional difficulty in the initiation of movements with impaired activation of the anterior cingulum, putamen, prefrontal cortex, and supplementary motor area (Playford et al).

We would repeat that *in our experience, a quantitative reduction in all activity is the most frequent of all psychobehavioral alterations in patients with cerebral disease*, particularly in those with involvement of the anterior parts of the frontal lobes. There are fewer thoughts, fewer words uttered, and fewer movements per unit of time. That this is not a purely motor phenomenon is disclosed in conversation with the patient, who seems to perceive and think more slowly, to make fewer associations with a given idea, to initiate speech less frequently, and to exhibit less inquisitiveness and interest. This reduction in psychomotor activity is recognized as a personality change by the family.

Depending on how this state is viewed, it may be interpreted as a heightened threshold to stimulation, inattentiveness or inability to maintain an attentive attitude, impaired thinking, apathy, or lack of impulse (*abulia*). In a sense, all are correct, for each represents a different aspect of the reduced mental activity. Clinicoanatomic correlates are inexact, but bilateral lesions deep in the septal region (basal frontal, as sometimes occur with bleeding from an anterior communicating aneurysm) have resulted in the most striking lack of impulse, spontaneity, and concentration (Fig. 25-3). An impairment of learning and memory functions may be added. Typically the patient is fully conscious, is wide awake, and looks around—i.e., is visually attentive. Upon recovery, memory is retained for all that happened. In this respect *abulia* differs from stupor and hypersonomnolence.

Patients who exhibit *abulia* are difficult to test because they respond slowly or not at all to every type of test. Yet on rare occasions, when intensely stimulated, they may speak and act normally. It is as though some energizing mechanism (possibly striatocortical), different from the reticular activating system of the upper brainstem, were impaired.

Quite apart from this abulic syndrome, which has already been discussed in relation to coma and to extensive lesions of the frontal lobes (Chaps. 17 and 22), there are lesser degrees of it, in which a lively, sometimes volatile person has been rendered placid (hypobulic) by a disease of the nervous system. This corresponds to lesser degrees of frontal lobe damage than that described above with septal lesions; most often the damage is bilateral but sometimes on the left only, as discussed in Chap. 22. Diseases as diverse as hydrocephalus, glioma, strokes, trauma, and encephalitis may be causative. Formerly, the most consistent changes of this type were observed following bilateral prefrontal leukotomy. Barris and Schuman and many others have documented states of extreme placidity with lesions of the anterior cingulate gyri. Unlike the case in depression, the mood is neutral; the patient is apathetic rather than depressed.

The alteration in emotional behavior described above differs from that observed in the *Klüver-Bucy syndrome*, which results
from total bilateral temporal lobectomy in adult rhesus monkeys (see also page 397). While these animals were rather placid and lacked the ability to recognize objects visually (they could not distinguish edible from inedible objects), they had a striking tendency to examine everything orally, were unusually alert and responsive to visual stimuli (they touched or mouthed every object within their visual fields), became hypersexual, and increased their food intake. This constellation of behavioral changes has been sought in human beings—for example, after removal of the temporal lobes—but the complete syndrome has been described only infrequently (Marlowe et al; Terzian and Dalle). Pillieri and Poecck have collected cases that have come closest to reproducing the syndrome (Fig. 25-3). Unfortunately, many human examples have occurred in conjunction with diffuse diseases (Alzheimer and Pick cerebral atrophies, meningoencephalitis due to toxoplasmosis, herpes simplex, or AIDS) and hence are of less use for anatomic analysis. With bitemporal surgical ablations, placidity and enhanced oral behavior were the most frequent consequences; altered sexual behavior and visual agnosia were less frequent. In all patients who showed placidity and an amnestic state, the hippocampi and medial parts of the temporal lobe had been destroyed, but not the amygdaloid nuclei.

Perhaps the most consistent type of reduced emotionality in humans, albeit one that is restricted in scope, is that associated with acute lesions (usually infarcts or hemorrhages) in the right or non-dominant parietal lobe. Not only is the patient indifferent to the paralysis but, as Bear points out, he is unconcerned about his other diseases as well as personal and family problems, is less able to interpret the emotional facial expressions of others, and is inattentive in general. Dimond and coworkers interpret this to mean that the right hemisphere is more involved in affective-emotional experience than the left, which is committed to language. Observations derived from the study of split-brain patients and from selective anesthetization of the cerebral hemispheres by intracarotid injection of amobarbital (Wada test) lend some support to this probably oversimplified view. Rarely, lesions of the left (dominant) hemisphere appear to induce the opposite effect—a frenzied excitement lasting for days or weeks.

The full range of placidity reactions in neurology has not been catalogued. Unfortunately, neurologists and psychiatrists have tended to neglect this aspect of behavior.

Altered Sexuality

The normal pattern of sexual behavior in both males and females may be altered by cerebral disease quite apart from impairment due to obvious physical disability or to diseases that destroy or isolate the segmental reflex mechanisms (see Chap. 26).

Hypersexuality in men or women is a rare but well-documented complication of neurologic disease. It has long been believed that lesions of the orbital frontal lobes may remove moral-ethical restraints and lead to indiscriminate sexual behavior, and that superior frontal lesions may be associated with a general loss of initiative that reduces all impulsivity, including sexual. In rare cases, extreme hypersexuality marks the onset of encephalitis or develops gradually with tumors of the temporal region. Possibly the limbic parts of the brain are disinhibited, the ones from which MacLean and Ploog could evoke penile erection and orgasm by electrical stimulation (medial dorsal thalamus, medial forebrain bundle, and septal preoptic region). In humans, Heath has observed that stimulation of the ventroseptal area (through depth electrodes) evokes feelings of pleasure and lust. Also, Gorman and Cummings have described two patients who became sexually disinhibited after a shunt catheter had perforated the dorsal septal region. This is in keeping with the experience of Heath and Fitzjarrell, who found that infusion of acetylcholine into the septal region (an experimental treatment for Parkinson disease) produced euphoria and orgasm, and with Heath’s recordings from the septum of patients during sexual intercourse, showing greatly increased activity with spikes and slow waves. Perhaps these are examples of a true overdrive of libido, as contrasted with simple disinhibition of sexual behavior. However, we know of no case in which a stable lesion that caused abnormal sexual behavior has been studied carefully by sections of the critical parts of the brain. In clinical practice, the commonest cause of disinhibited sexual behavior, next to the aftermaths of head injury and cerebral hemorrhage, is the use of dopaminergic drugs in Parkinson disease. Mania may do the same.

Hypersexuality, meaning loss of libido, is most often due to a depressive illness. However, certain medications—notably antihypertensive, anticonvulsant, serotoninergic antidepressant, and neuroleptic drugs—may be responsible in individual patients. A variety of cerebral diseases may also have this effect, in parallel with a loss of interest and drive in a number of spheres.

Lesions that involve the tuberoinfundibular region of the hypothalamus are known to cause specific disturbances in sexual function. If such lesions are acquired early in life, pubertal changes are prevented from occurring; or, hamartomas of the hypothalamus, as in von Recklinghausen neurofibromatosis and tuberous sclerosis, may cause sexual precocity. Autonomic neuropathies and lesions involving the sacral parts of the parasympathetic system, the commonest being prostatectomy, may abolish normal sexual performance but do not alter libido or orgasm.

Blumer and Walker have reviewed the literature on the association of epilepsy and abnormal sexual behavior. They note that sexual arousal as an ictal phenomenon is apt to occur in relation to temporal lobe seizures, particularly when the discharging focus is in the mediotemporal region. These authors also cite the high incidence of global hypersexuality in patients with temporal lobe epilepsy. Temporal lobectomy in such patients has sometimes been followed by a period of hypersexuality.

Acute Fear, Anxiety, Elation, and Euphoria

The phenomenon of acute fear and anxiety occurring as a prelude to or part of a seizure is familiar to every physician. Williams’s study, already mentioned, is of particular interest; from a series of about 2000 epileptics, he was able to cull 100 patients in whom an emotional experience was part of the seizure. Of the latter, 61 experienced feelings of fear and anxiety and 21 experienced depression. Daly has made similar observations. These clinical data call to mind the effects that had been noted by Penfield and Jasper when they stimulated the upper, anterior, and inferior parts of the temporal lobe and cingulate gyrus during surgical procedures; frequently the patient described feelings of strangeness, uneasiness, and fear. In most instances, consciousness was variably impaired at the same time, and some patients had hallucinatory experiences as well.

In these cortical stimulations, neuronal circuits subserving fear are coextensive with those of anger; both are thought to lie in the medial part of the temporal lobe and amygdala, as discussed earlier. Both in animals and in humans, electrical stimulation in this region...
can arouse each emotion, but the circuitry subserving fear appears to be located lateral to that of anger and rage. Destruction of the central part of the amygdaloid nuclear complex abolishes fear reactions. These nuclei are connected to the lateral hypothalamus and midbrain tegmentum, regions from which Monroe and Heath as well as Nashold and associates have been able to evoke feelings of fear and anxiety by electrical stimulation.

Depression is less frequent as an ictal emotion, although it occurs often enough as an interictal phenomenon (Benson et al). Of interest is the observation that lesions of the dominant hemisphere are more likely than nondenominant ones to be attended by an immediate pervasive depression of mood, disproportionate to the degree of severity of physical disability (Robinson et al). We are inclined to the view that the onset of depression after a stroke is a reaction to disability, i.e., a reactive depression, akin to that which follows myocardial infarction (Chap. 57).

Odd mixtures of depression and anxiety are often associated with temporal lobe tumors and less often with tumors of the hypothalamus and third ventricle (see review by Alpers), and they sometimes occur at the onset of a degenerative disease, such as multiple system atrophy.

Elation and euphoria are less well documented as limbic phenomena, nor has this elevation in mood in some patients with multiple sclerosis ever been adequately explained. Feelings of pleasure and satisfaction as well as “stirring sensations” are unusual but well-described emotional experiences in patients with temporal lobe seizures, and this type of affective response, like that of fear, has been elicited by stimulating several different parts of the temporal lobe (Penfield and Jasper). In states of hypomania and mania, every experience may be colored by feelings of delight and pleasure and a sense of power, and the patient may remember these experiences after he has recovered.

Differential Diagnosis of Perturbations in Emotion and Affect

Aside from clinical observation, there are no reliable means of evaluating or quantifying the emotional disorders described above. While neurologic medicine has done little more than describe and classify some of the clinical states dominated by emotional derangements, knowledge of this type is nonetheless of both theoretical and practical importance. In theory, it prepares one for the next step, of passing from a superficial to a deeper order of inquiry, where questions of pathogenesis and etiology can be broached. Practically, it provides certain clues that are useful in differential diagnosis. A number of particular neurologic possibilities must always be considered when one is confronted with one of the following clinical states.

Uninhibited Laughter and Crying and Emotional Lability As indicated earlier, one may confidently assume that the syndrome of forced or spasmodic laughing and crying signifies cerebral disease and more specifically bilateral disease of the corticobulbar tracts (see Table 25-2). Usually the motor and reflex changes of spastic bulbar (pseudobulbar) palsy described on page 426 are associated, especially heightened facial and mandibular reflexes (“jaw jerk”) and often corticospinal tract signs in the limbs as well. Extreme emotional lability also indicates bilateral cerebral disease, although only the signs of unilateral disease may be apparent clinically. The most common pathologic bases for these clinical states are lacunar infarction or other cerebrovascular lesions, diffuse hypoxic-hypoxemic encephalopathy, amyotrophic lateral sclerosis, and multiple sclerosis, as already indicated; but in a number of less common processes, such as progressive supranuclear palsy and Wilson disease, it may be quite a prominent feature. Abrupt onset, of course, points to vascular disease.

Placidity and Apathy These may be the earliest and most important signs of cerebral disease. Clinically, placidity and apathy must be distinguished from the akinesia or bradykinesia of Parkinson disease and the reduced mental activity of depressive illness. Here, Alzheimer disease, normal-pressure hydrocephalus, and frontal–corpus callosum tumors are the most common pathologic states underlying apathy and placidity, but these disturbances may complicate a variety of other frontal and temporal lesions, such as those occurring with demyelinating disease or as an aftermath of ruptured anterior communicating aneurysm.

Outbursts of Rage and Violence Most often such an outburst is but another episode in a lifelong sequence of sociopathic behaviors (see Chap. 56). More significance attaches to its abrupt appearance as a sudden departure from an individual’s normal personality. If an outburst of rage accompanies a seizure, the rage should be viewed as the consequence of the disruptive effect of seizure activity on temporal lobe function; however, as indicated earlier, an outburst of uncontrolled rage and violence is only rarely a manifestation of psychomotor epilepsy. Lesser degrees of poorly directed combative behavior, as part of ictal or postictal automatism, are more common. Rarely, rage and aggressivity are expressive of an acute neurologic disease that involves the mediotemporal and orbitofrontal regions, such as a glioma. We have several times observed such states in the course of a dementing disease and in a stable individual as a transient expression of an obscure encephalopathy.

Rage reactions with continuous violent activity must be distinguished from mania, in which there is flight of ideation to the point of incoherence, euphoric or irritable mood, and incessant psychomotor activity; from organic drivenness, in which continuous motor activity, accompanied by no clear ideation occurs, usually in a child, as an aftermath of encephalitis; and from extreme instances of akathisia, where incessant restless movements and pacing may occur in conjunction with extrapyramidal symptoms.

Extreme Fright and Agitation Here the central problem must be clarified by determining whether the patient is delirious (clouding of consciousness, psychomotor overactivity, and hallucinations), deluded (schizophrenia), manic (overactive, flight of ideas), or experiencing an isolated panic attack (palpitation, trembling, feeling of suffocation, etc.). Rarely does panic prove to be an expression of temporal lobe epilepsy. In an adult without a charactologic trait of anxiety, an acute panic attack may signify the onset of a depressive illness or schizophrenia.

Bizarre Ideation Developing over Weeks or Months While these symptoms are usually due to a psychosis (schizophrenia or manic-depressive disease), one should consider a tumor or other lesion of the temporal lobe, particularly when accompanied by psychomotor seizures, aphasic symptoms, rotatory vertigo (rare), and quadranthic visual field defects. Such states have also been described in hypothalamic disease, suggested by somnolence, diabetes insipidus, visual field defects, and hydrocephalus (see Chap. 27).

CHAPTER 26

DISORDERS OF THE AUTONOMIC NERVOUS SYSTEM, RESPIRATION, AND SWALLOWING

The human internal environment is regulated in large measure by the integrated activity of the autonomic nervous system and endocrine glands. Their visceral and homeostatic functions, essential to life and survival, are involuntary. Why nature has divorced them from volition is an interesting question. One would like to think that the mind, being preoccupied with discriminative, moral, and esthetic matters, should not have to be troubled with such mundane functions as breathing, regulation of heart rate, lactation, swallowing, and sleeping. Claude Bernard expressed this idea in more sardonic terms when he wrote, “nature thought it prudent to remove these important phenomena from the caprice of an ignorant will.”

While relatively few neurologic diseases exert their effects primarily or exclusively on the autonomic-neuroendocrine axis, there are numerous medical diseases that implicate this system in some way—hypertension, asthma, and certain dramatic disorders of cardiac conduction, such as ventricular tachycardia, to name some of the important ones. And many more general neurologic diseases involve the autonomic nervous system to a varying extent, giving rise to symptoms such as syncpe, sphincteric dysfunction, pupillary abnormalities, diaphoresis, and disorders of thermoregulation. Also, a wide variety of commonly used pharmacologic agents influence autonomic functions, making them the concern of every physician. Finally, in addition to their central role in visceral innervation, autonomic parts of the neuraxis and parts of the endocrine system are utilized in all emotional experience and its display as discussed in Chap. 25.

Breathing is unique among autonomic nervous system functions. While continuous throughout life, it is not altogether automatic being partly under volitional control. Current views of the central and peripheral control of breathing, and the ways in which it is altered by certain diseases are of considerable interest to neurologists, if for no other reason than the frequency of respiratory failure resulting from numerous neurologic conditions such as coma, cervical spinal cord injury, and neuromuscular diseases—the main ones being Guillain-Barré syndrome, myasthenia gravis, amyotrophic lateral sclerosis, and polymyelitis. Treatment of the resultant respiratory failure constitutes a most important part of the specialty of neurointensive care. Many of these same comments pertain to the function of swallowing, which is largely automatic and continues at regular intervals even in sleep, but can also be initiated voluntarily. Furthermore, swallowing fails in similar ways to breathing as a consequence of certain neurologic diseases.

The autonomic and endocrine systems, though closely related, give rise to disparate clinical syndromes, so that each is accorded a separate chapter. This chapter deals with the autonomic nervous system and the next with the hypothalamus and neuroendocrine disorders. The following discussion of anatomy and physiology serves as an introduction to both chapters.

Anatomic Considerations

The most remarkable feature of the autonomic nervous system (also called the visceral, vegetative, or involuntary nervous system) is that a major part of it is located outside the cerebrospinal system, in proximity to the visceral structures that it innervates. This position alone seems to symbolize its relative independence from the cerebrospinal system. Also, in distinction to the somatic neuromuscular system, where a single motor neuron bridges the gap between the central nervous system (CNS) and the effector organ, in the autonomic nervous system there are always two efferent neurons serving this function—one (preganglionic) arising from its nucleus in the brainstem or spinal cord and the other (postganglionic) arising from specialized nerve cells in peripheral ganglia.

This fundamental anatomic feature is illustrated in Fig. 26-1. From a strictly anatomic point of view, the autonomic nervous system is divided into two parts: the craniosacral, or parasympathetic, and the thoracolumbar, or sympathetic (Figs. 26-2, 26-3, and 26-4). Functionally, the two parts are complementary in maintaining a balance in the tonic activities of many visceral structures and organs. This rigid separation into sympathetic and parasympathetic parts, while useful for purposes of exposition, is not altogether absolute physiologically. For example, Blessing points out that the scheme does not provide a thorough explanation for each of the homeostatic functions that are under control of complex systems of central and peripheral neurons. And from a neurologist’s perspective, the two components are often affected together. Nonetheless, the notion of a balanced autonomic system has stood the test of time and remains a valid neuroanatomic and neurophysiologic concept.

The Parasympathetic Nervous System (Fig. 26-2) There are two divisions of the parasympathetic nervous system—cranial and sacral. The cranial division originates in the visceral nuclei of the midbrain, pons, and medulla. These nuclei lie in close proximity to the somatic afferent nuclei and include the Edinger-Westphal pupillary nucleus, superior and inferior salivatory nuclei, dorsal motor nucleus of the vagus, and adjacent reticular nuclei.

Axons (preganglionic fibers) of the visceral cranial nuclei course through the oculomotor, facial, glossopharyngeal, and vagus nerves. The preganglionic fibers from the Edinger-Westphal nucleus traverse the oculomotor nerve and synapse in the ciliary ganglion in the orbit; axons of the ciliary ganglion cells innervate the ciliary muscle and pupillary sphincter (see Fig. 14-7). The preganglionic fibers of the superior salivatory nucleus enter the facial nerve and, at a point near the geniculate ganglion, form the greater superficial petrosal nerve, through which they reach the sphenopalatine ganglion; postganglionic fibers from the cells of this ganglion innervate the lacrimal gland (see also Fig. 47-3). Other fibers
of the facial nerve traverse the tympanic cavity as the chorda tympani and eventually join the submandibular ganglion; cells of this ganglion innervate the submandibular and sublingual glands. Axons of the inferior salivatory nerve cells enter the glossopharyngeal nerve and reach the otic ganglion through the tympanic plexus and lesser superficial petrosal nerve; cells of the otic ganglion send fibers to the parotid gland. Preganglionic fibers, derived from the dorsal motor nucleus of the vagus and adjacent visceral nuclei in the lateral reticular formation, enter the vagus nerve and terminate in ganglia situated in the walls of many thoracic and abdominal viscera; the ganglionic cells give rise to short postganglionic fibers that activate smooth muscle and glands of the pharynx, esophagus, and gastrointestinal tract (up to the descending colon) and of the heart, pancreas, liver, gallbladder, kidney, and ureter.

The sacral part of the parasympathetic system originates in the lateral horn cells of the second, third, and fourth sacral segments. Axons of these sacral neurons, constituting the preganglionic fibers, traverse the sacral nerves and synapse in ganglia that lie within the walls of the distal colon, bladder, and other pelvic organs. Thus, the sacral autonomic neurons, like the cranial ones, have long preganglionic and short postganglionic fibers—a feature that permits a circumscribed influence upon the target organ.

Probably the neurons that activate striated muscle differ from those that innervate glands and smooth muscle. In the sacral segments, for example, the neurons that activate the external sphincters (voluntary muscle) differ from others that supply the smooth muscle of bladder and rectocolon. In 1900, Onufrowicz (calling himself Onuf) described a discrete, compact group of relatively small cells in the anterior horns of sacral segments 2 to 4. These neurons were originally thought to be autonomic in function, mainly because of their histologic features. There is now more compelling evidence that they are somatomotor, innervating the skeletal muscle of the external urethral and anal sphincters (Holstege and Tan). Neurons in the intermediolateral cell column of sacral cord segments innervate the detrusor of the bladder wall. In passing, it is worth noting that in motor system disease, in which bladder and bowel functions are usually preserved until late in the disease, the neurons in Onuf’s nucleus, in contrast to other somatomotor neurons in the sacral cord, tend not to be involved in the degenerative process (Mannen et al).

**The Sympathetic Nervous System** (Fig. 26-3) The preganglionic neurons of the sympathetic division originate in the intermediolateral cell column of the spinal gray matter, from the eighth cervical to the second lumbar segments. Low and Dyck have estimated that each segment of the cord contains about 5000 lateral horn cells and that, in late adult life, there is an attrition of 5 to 7 percent per decade. Axons of the nerve fibers originating in the intermediolateral column are of small caliber and are myelinated; when grouped, they form the white communicating rami. These preganglionic fibers synapse with the cell bodies of the postganglionic neurons, which are collected into two large ganglionated chains or cords, one on each side of the vertebral column (paravertebral ganglia), and several single prevertebral ganglia.

Axons of the sympathetic ganglion cells are also of small caliber but are unmyelinated. Most of the postganglionic fibers pass
Figure 26-2. The parasympathetic (craniosacral) division of the autonomic nervous system. Preganglionic fibers extend from nuclei of the brainstem and sacral segments of the spinal cord to peripheral ganglia. Short postganglionic fibers extend from the ganglia to the effector organs. The lateral-posterior hypothalamus is part of the supranuclear mechanism for the regulation of parasympathetic activities. The frontal and limbic parts of the supranuclear regulatory apparatus are not indicated in the diagram (see text). (Reproduced by permission from Noback CL, Demarest R: The Human Nervous System, 3rd ed. New York, McGraw-Hill, 1981.)
via gray communicating rami to spinal nerves of T5 to L2; they supply blood vessels, sweat glands, and hair follicles and also form plexuses that supply the heart, bronchi, kidneys, intestines, pancreas, bladder, and sex organs. The postganglionic fibers of the prevertebral ganglia (located in the posterior abdomen rather than paravertebrally) form the hypogastric, splanchnic, and mesenteric plexuses, which innervate the glands, smooth muscle, and blood vessels of the abdominal and pelvic viscera (Figs. 26-1 and 26-4).

The sympathetic innervation of the adrenal medulla is unique in that its secretory cells receive preganglionic fibers directly, via

Figure 26-3. The sympathetic (thoracolumbar) division of the autonomic nervous system. Preganglionic fibers extend from the intermediolateral nucleus of the spinal cord to the peripheral autonomic ganglia, and postganglionic fibers extend from the peripheral ganglia to the effector organs, according to the scheme in Fig. 26-1. (Reproduced by permission from Noback CL, Demarest R: The Human Nervous System, 3rd ed. New York, McGraw-Hill, 1981.)
Paravertebral sympathetic outflow from the spinal cord. Preganglionic fibers of ganglia that are placed beyond the limits of the usual preganglionic visceral connections; the upper lumbar ganglia supply the abdominal visceral plexuses, from the fifth to the ninth or tenth thoracic ganglia. The lowermost thoracic ganglia have no abdominal sympathetic nerves are derived from the upper thoracic ganglion and the abdominal visceral plexuses, from the fifth to the ninth or tenth thoracic ganglia. The lowermost thoracic ganglia have no abdominal visceral connections; the upper lumbar ganglia supply the descending colon, pelvic organs, and legs.

The terminals of autonomic nerves and their junctions with smooth muscle and glands have been more difficult to visualize and study than the motor end plates of striated muscle. As the postganglionic axons enter an organ, usually via the vasculature, they ramify into many smaller branches and disperse, without a Schwann cell covering, to innervate the smooth muscle fibers, the glands, and, in largest number, the small arteries, arterioles, and precapillary sphincters (see Burnstock). Some of these terminals penetrate the smooth muscle of the arterioles; others remain in the adventitia. At the ends of the postganglionic fibers and in part along their course there are swellings that lie in close proximity to the sarcolemma or gland cell membrane; often the muscle fiber is grooved to accommodate these swellings. The axonal swellings contain synaptic vesicles, some clear and others with a dense granular core. The clear vesicles contain acetylcholine, and those with a dense core contain catecholamines, particularly norepinephrine (Falck). This is well illustrated in the iris, where nerves to the dilator muscle (sympathetic) contain dense-core vesicles and those to the constrictor (parasympathetic), clear vesicles. A single nerve fiber innervates multiple smooth muscle and gland cells.

Visceral Afferents Somewhat arbitrarily, anatomists have declared the autonomic nervous system to be purely efferent motor and secretory in function. However, most autonomic nerves are mixed, also containing afferent fibers that convey sensory impulses from the viscera and blood vessels. The cell bodies of these sensory neurons lie in the posterior root sensory ganglia; some central axons of these ganglionic cells synapse with lateral horn cells of the spinal cord and subserve visceral reflexes; others synapse in the dorsal horn and convey or modulate impulses for conscious sensation. Secondary afferents carry sensory impulses to certain brainstem nuclei, particularly the nucleus tractus solitarius, as described below, and the thalamus via the lateral spinothalamic and polysynaptic pathways.

The Central Regulation of Visceral Function Integration of autonomic function takes place at two levels, the brainstem and the cerebrum. In the brainstem, the main visceral afferent nucleus is the nucleus tractus solitarius (NTS). Cardiovascular, respiratory, and gastrointestinal afferents, carried in cranial nerves X and IX via the nodose and petrosal ganglia, terminate on specific subnuclei of the NTS. The caudal subnuclei are the primary receiving site for visceral sensory fibers; other less well defined areas receive baroreceptor and chemoreceptor information. The caudal NTS integrates these signals and projects to a number of critical areas in the hypothalamus, amygdala, and insular cortex, involved primarily in cardiovascular control, as well as to the pontine and medullary nuclei controlling respiratory rhythms. The NTS therefore serves a critical integratory function for both circulation and respiration, as described further on.

An important advance in our understanding of the autonomic nervous system occurred with the discovery of autonomic regulating functions of the hypothalamus. Small, insignificant-looking nuclei in the walls of the third ventricle and in buried parts of the limbic cortex, formerly judged to have purely olfactory functions, are now known to have rich bidirectional connections with autonomic centers in various parts of the nervous system. In fact, the hypothalamus serves as the integrating mechanism of the autonomic nervous system and limbic system, as indicated in Chap. 25. The regulatory activity of the hypothalamus is accomplished in two ways—through direct pathways that descend to particular groups of cells in the brainstem and spinal cord and through the pituitary and thence to other endocrine glands. The supranuclear regulatory apparatus of the hypothalamus includes three main cerebral struc-
tures: the frontal lobe cortex, the insular cortex, and the amygdaloid and adjacent nuclei.

The ventromedial prefrontal and cingulate cortices function as the highest levels of autonomic integration. Stimulation of one frontal lobe may evoke changes in temperature and sweating in the contralateral arm and leg; massive lesions here, which usually cause a hemiplegia, may modify the autonomic functions in the direction of either inhibition or facilitation. Lesions involving the posterior part of the superior frontal and anterior part of the cingulate gyri (usually bilateral, occasionally unilateral) result in loss of voluntary control of the bladder and bowel (see page 393). Most likely a large contingent of these fibers terminates in the hypothalamus, which, in turn, sends fibers to the brainstem and spinal cord. The descending spinal pathways from the hypothalamus are believed to lie ventromedial to the corticospinal fibers.

The insular cortex receives projections from the NTS, the parabrachial nucleus of the pons, and the lateral hypothalamic nuclei. Direct stimulation of the insula produces cardiac arrhythmias and abrachial nucleus of the pons, and the lateral hypothalamic nuclei. Stimulation of the insula produces cardiac arrhythmias and abrachial nucleus of the pons, and the lateral hypothalamic nuclei.

The function of the autonomic nervous system in its regulation of the visceral organs is to a high degree independent. When the autonomic nerves are interrupted, these organs continue to function (the organism survives), but they are no longer as effective in maintaining homeostasis and adapting to the demands of changing internal conditions and external stresses.

It was learned long ago that most viscera have a double nerve supply, sympathetic and parasympathetic, and that in general these two parts of the autonomic nervous system exert opposite effects. For example, the effects of the sympathetic nervous system on the heart are excitatory and those of the parasympathetic inhibitory. However, some structures—sweat glands, cutaneous blood vessels, and hair follicles—receive only sympathetic postganglionic fibers, and the adrenal gland, as indicated above, has only a preganglionic sympathetic innervation. Also, some parasympathetic neurons have been identified in sympathetic ganglia.

Neurohumoral Transmission All autonomic functions are mediated through the release of chemical transmitters. The modern concept of neurohumoral transmission had its beginnings in the early decades of the twentieth century. In 1921, Loewi discovered that stimulation of the vagus nerve released a chemical substance (“Vagustoff”) that slowed the heart. Later this substance was shown by Dale to be acetylcholine (ACh). Also in 1921, Cannon reported that stimulation of the sympathetic trunk released an epinephrine-like substance, which increased the heart rate and blood pressure. He named this substance “sympathin,” subsequently shown to be noradrenaline, or NE. Dale found that ACh had pharmacologic effects similar to those obtained by stimulation of parasympathetic nerves; he designated these effects as “parasympathomimetic.” These observations placed neurochemical transmission on solid ground and laid the basis for the distinction between cholinergic and adrenergic transmission in the autonomic nervous system.

The most important of the autonomic neurotransmitters are ACh and NE. ACh is synthesized at the terminals of axons and stored in presynaptic vesicles until it is released by the arrival of nerve impulses. ACh is released at the terminals of all presynaptic fibers (in both the sympathetic and parasympathetic ganglia) as well as at the terminals of all postganglionic parasympathetic and a few special postganglionic sympathetic fibers, mainly those subserving sweat glands. (Of course, ACh is also the chemical transmitter of nerve impulses to the skeletal muscle fibers.) Parasympathetic postganglionic fiber function is mediated by two distinct
types of ACh receptors—nicotinic and muscarinic, so named by Dale because the choline-induced responses were similar either to those of nicotine or to those of the alkaloid muscarine. The post-ganglionic parasympathetic receptors are located within the innervated organ and are muscarinic; i.e., they are antagonized by atropinic drugs. The receptors in ganglia, like those of skeletal muscle, are nicotinic; they are not blocked by atropine but by other agents (e.g., tubocurarine).

It is likely that more than ACh is involved in nerve transmission at a ganglionic level. Many peptides—substance P, enkephalins, somatostatin, vasoactive intestinal peptide, adenosine triphosphate (ATP), and most recently nitric oxide—have been identified in the autonomic ganglia, localizing in some cases to the same cell as ACh. (This negates “Dale’s law,” which stipulates that one neuron elaborates only one neurotransmitter.) Particular neuronal firing rates appear to cause the preferential release of one or another of these substances. Most of the neuropeptides exert their postsynaptic effects through the G-protein transduction system which utilizes adenylcyclase or phospholipase C as intermediaries. The neuropeptides act as modulators of neural transmission, although their exact function in many cases remains to be determined.

With two exceptions, postganglionic sympathetic fibers release only NE at their terminals. The sweat glands and some blood vessels in muscle are innervated by postganglionic sympathetic fibers, but their terminals, as mentioned, release ACh. The NE that is discharged into the synaptic space activates specific adrenergic receptors on the postsynaptic membrane of target cells.

Adrenergic receptors are of two types, classified originally by Ahlquist as alpha and beta. In general, the alpha receptors mediate vasoconstriction, relaxation of the gut, and dilatation of the pupil; beta receptors mediate vasodilatation, especially in muscles; relaxation of the bronchi; and an increased rate and contractility of the heart. Each of these receptors is subdivided further into two types. Alpha1 receptors are postsynaptic; alpha2 receptors are situated on the presynaptic membrane and, when stimulated, diminish the release of the transmitter. Beta1 receptors are for, all practical purposes, limited to the heart; their activation increases the heart rate and contractility. Beta2 receptors, when stimulated, relax the smooth muscle of the bronchi and of most other sites, including the blood vessels of skeletal muscle. A comprehensive account of neurohumoral transmission and receptor function can be found in the review by Hoffman and colleagues and in the monograph by Cooper and colleagues.

Discussed in the following pages are the ways in which the two divisions of the autonomic nervous system, acting in conjunction with the endocrine glands, maintain the homeostasis of the organism. As stated above, the integration of these two systems is achieved primarily in the hypothalamus. In addition, the endocrine glands are influenced by circulating catecholamines, and some of them are innervated by adrenergic fibers, which terminate not only on blood vessels but also, in some cases, directly on secretory cells. These autonomic-endocrine relations are elaborated in Chap. 27.

Regulation of Blood Pressure

As was indicated briefly in Chap. 18, blood pressure depends on the adequacy of intravascular blood volume, on systemic vascular resistance, and on the cardiac output. Both the autonomic and endocrine systems influence the muscular, cutaneous, and mesenteric (splanchnic) vascular beds, pulse rate, and stroke volume of the heart. Together, these actions serve to maintain normal blood pressure and allow reflex maintenance of blood pressure with changes in body position. Two types of baroreceptors function as the afferent component of this reflex arc by sensing pressure gradients across the walls of large blood vessels. Those in the carotid sinus and aortic arch are sensitive to reductions in pulse pressure (the difference between systolic and diastolic blood pressure), while those in the right heart chambers and pulmonary vessels respond more to alterations in blood volume. The carotid sinus baroreceptors are rapidly responsive and capable of detecting beat-to-beat changes, in contrast to the aortic arch nerves, which have a longer response time and discriminate only the larger and more prolonged alterations in pressure.

The nerves arising from these receptors are small-caliber, thinly myelinated fibers that course in cranial nerves IX and X and terminate in the NTS. In response to increased stimulation of these receptors, vagal efferent activity is reduced, resulting in reflex cardiovascular acceleration. This is accomplished through polysynaptic connections between the NTS and the dorsal motor nucleus of the vagus; it is from this structure that vagal neurons project to the sinoatrial node. Increased systemic vascular resistance is effected concurrently through parallel connections between the NTS and the mediullary pressor areas that project, in turn, to the intermediolateral cells of the midthoracic cord. The main sympathetic outflow from these segments is via the greater splanchnic nerve to the celiac ganglion, the postganglionic nerves of which project to the capacitance vessels of the gut. The splanchnic capacitance veins act as a reservoir for as much as 20 percent of the total blood volume, and interruption of the splanchnic nerves results in severe postural hypotension. After a high-carbohydrate meal there is a marked hyperpermia of the gut and compensatory peripheral vasoconstriction in the muscles and skin. It has also been noted that the mesenteric vascular bed is responsive to the orthostatic redistribution of blood volume but not to mental stress.

The opposite response to the one described above, namely bradycardia and hypotension, results when vagal tone is enhanced and sympathetic tone reduced. This response can be triggered by baroreceptors, or it may arise from cerebral stimuli such as fear or sight of blood in susceptible individuals.

Two slower-acting humoral mechanisms regulate blood volume and complement the control of systemic vascular resistance. Pressure-sensitive renal juxtaglomerular cells release renin, which stimulates production of angiotensin and influences aldosterone production, both of which effect an increase of blood volume. Of lesser influence in the control of blood pressure is antidiuretic hormone, discussed in the next chapter; but the effects of this peptide become more important when autonomic failure forces a dependence on secondary mechanisms for the maintenance of blood pressure. More recently, in addition to its presence in autonomic ganglia, nitric oxide has been found to have an important local role in maintaining vascular tone, mainly by way of attenuating the response to sympathetic stimulation. The extent to which this latter function is under neural control is not clear.

Emergency and Alarm Reactions Inasmuch as the autonomic nervous system and the adrenal glands were accepted for many years as the neural and humoral basis of all instinctive and emotional behavior, it is remarkable how little sound information has been acquired about their roles in disease. In states of chronic anxiety and acute panic reactions, depressive psychosis, mania, and schizophrenia, all of which are characterized by an altered emo-
Posture and Breathing Responses of Blood Pressure and Heart Rate to Changes in

Table 26-1. A scheme for the examination of pupillary abnormal-

different function. These are described below and are summarized in

thetic function and others to parasympathetic or baroreceptor af-
certain ones are particularly sensitive to abnormalities of sympa-
togenesis, no consistent autonomic or endocrine dysfunction has
been demonstrated except perhaps for diminished responses of

growth hormone in panic disorders. This has been disappointing,
since Cannon, with his emergency theory of sympathoadrenal ac-
tion, had provided such a promising concept of the neurophysi-
ology of acute emotion, and Selye had extended this theory so plau-
sibly to explain all the reactions to stress in animals and humans.

According to these theories, strong emotion, such as anger or fear,
excites the sympathetic nervous system and the adrenal cortex [via
corticotropin releasing factor (CRF) and adrenocorticotropin hor-
mone (ACTH)], which are under direct neural as well as endocrine
control. These sympathoadrenal reactions are brief and sustain the
animal in “flight or fight” (pages 443 and 447). Animals deprived
of adrenal cortex or human beings with Addison disease cannot
 tolerate stress because they are incapable of mobilizing both the
adrenal medulla and adrenal cortex. Prolonged stress and produc-
tion of ACTH activates all the adrenal hormones, referred to col-
lectively as steroids (glucocorticoids, mineralocorticoids, and ad-
renocorticoids).

In animals, exercise, cold, oxygen lack, and surgical injury are
all said to evoke the same sympathoadrenal reactions as anger or
fear. Selye’s extension of Cannon’s theory to his more compre-
prehensive theory of stress, although attractive, has received little sup-
port. Critics have pointed out that the conditions to which his ex-
perimental animals had been subjected are so different from human
disease that conclusions as to the similarities of the two cannot be
drawn. More critical studies of the anatomy and physiology of the
hypothalamus, hypophysis, adrenal glands, and autonomic nervous
system are still needed to fully test these hypotheses.

Tests for Abnormalities of the Autonomic Nervous System

With few exceptions, such as testing pupillary reactions and ex-
amination of the skin for abnormalities of color and sweating, the
neurologist tends to be casual in evaluating the function of the
autonomic nervous system. Nonetheless, several simple but in-
formative tests can be used to confirm one’s clinical impressions
and to elicit abnormalities of autonomic function that may aid in
diagnosis. A combination of tests is usually necessary, because
certain ones are particularly sensitive to abnormalities of sympa-
thetic function and others to parasympathetic or baroreceptor af-
ferent function. These are described below and are summarized in
Table 26-1. A scheme for the examination of pupillary abnormal-

dies has been presented in Fig. 14-8.

Responses of Blood Pressure and Heart Rate to Changes in
Posture and Breathing These are among the simplest and most
important tests of autonomic function and are currently automated
in most laboratories. McLeod and Tuck state that in changing from
the recumbent to the standing position, a fall of more than 30
mmHg systolic and 15 mmHg diastolic is abnormal; others give
figures of 20 and 10 mmHg. They caution that the arm on which
the cuff is placed must be held horizontally when standing, so that
the decline in arm pressure will not be obscured by the added hy-
drostatic pressure.

The main cause of an orthostatic drop in blood pressure is
hypovolemia. In the context of recurrent fainting, however, an ex-
cessive drop reflects inadequate sympathetic vasoconstrictor ac-

tivity. The use of a tilt table, as described on page 330, is the most
sensitive means of inducing orthostatic changes and also elicits
these changes in patients prone to syncope from an oversensitive
cardiac reflex, i.e., one that produces vasodilation (so-called neu-
rocardiogenic syncope), as discussed in Chap. 18. In response to
the induced drop in blood pressure, the pulse rate (under vagal
control) normally increases. The failure of the heart rate to rise in
response to the drop in blood pressure with standing is the simplest
bedside indicator of vagal nerve dysfunction. In addition, the pulse,
after rising initially in response to upright posture, slows after about
15 beats to reach a stable rate by the 30th beat. The ratio of R–R
intervals in the electrocardiogram (ECG), corresponding to the 30th
and 15th beats (the 30:15 ratio), is an even more sensitive measure
of the integrity of vagal inhibition of the sinus node. A ratio in
nonelderly adults of less than 1.05 is usually abnormal, indicating
a loss of vagal tone.

Another simple procedure for quantitating vagal function con-
sists of measuring the variation in heart rate during deep breathing
(respiratory sinus arrhythmia). The ECG is recorded while the pa-
tient breathes at a regular rate of 6 to 12 per minute. Normally, the
heart rate varies by as many as 15 beats per minute or even more
between expiration and inspiration; differences of less than 10 beats
per minute may be abnormal. A yet more accurate test of vagal
function is the measurement of the ratio of the longest R–R interval
during forceful slow expiration to the shortest R–R interval during
inspiration, which allows the derivation of an expiration-inspiration
(E:I) ratio. This is the best-validated of all the pulse-rate measure-
ments, particularly since computerized methods can be used to dis-
play the spectrum of beat-to-beat ECG intervals during breathing.
Always, the results of these tests must be compared with those
obtained in normal individuals of the same age. Up to age 40, E:I
ratios of less than 1.2 (signifying a variation of 20 percent) are
abnormal. The ratio decreases with age, and markedly so beyond
age 60 (at which time it approaches 1.04 or less), as it does also in
the presence of even mild diabetic neuropathy. Thus the test results
must be interpreted cautiously in the elderly or diabetic individual.

Computerized methods of power spectral analysis may be used to
express the variance in heart rate as a function of the beat-to-beat
interval. Several power peaks are appreciated: one related to the
respiratory sinus arrhythmia and others that reflect baroreceptor and
cardiac sympathetic activity. All of these tests of heart rate variation
are usually combined with measurement of pulse and blood pres-
sure during the Valsalva maneuver, as described below, and with
the prolonged tilt table test, as described in Chap. 18.

In the Valsalva maneuver, the subject exhales into a manom-
eter or against a closed glottis for 10 to 15 s, creating a markedly
positive intrathoracic pressure. The sharp reduction in venous re-
turn to the heart causes a drop in cardiac output and in blood pres-
sure; the response on baroreceptors is to cause a reflex tachycardia
and, to a lesser extent, peripheral vasconstriction. With release of
intrathoracic pressure, the venous return, stroke volume, and blood
pressure rise to higher than normal levels; reflex parasympathetic
influence then predominates and a bradycardia results. Failure of
the heart rate to increase during the positive intrathoracic pressure
phase of the Valsalva maneuver points to sympathetic dysfunction,
and failure of the rate to slow during the period of blood pressure
overshoot points to a parasympathetic disturbance. In patients with
autonomic failure, the fall in blood pressure is not aborted during
the last few seconds of increased intrathoracic pressure, and there
is no overshoot of blood pressure when the breath is released.

Tests of Vasomotor Reactions Measurement of the skin tem-
perature is a useful index of vasomotor function. Vasomotor pa-

$^a$ Age-dependent response.

BP, blood pressure; E:I, expiration: inspiration.

SOURCE: Reproduced by permission from McLeod and Tuck.

Vasoconstriction induces an elevation of the blood pressure. This is the basis of the cold pressor test. In normal persons, immersing one hand in ice water for 1 to 5 min raises the systolic pressure by 15 to 20 mmHg and the diastolic pressure by 10 to 15 mmHg. Similarly, the sustained isometric contraction of a group of muscles (e.g., those of the forearm in handgrip) for 5 min normally increases the heart rate and the systolic and diastolic pressures by at least 15 mmHg. The response in both of these tests is reduced or absent with lesions of the sympathetic reflex arc, particularly of the efferent limb, but neither of these tests has been well quantitated or validated. The stress involved in doing mental arithmetic in noisy and distracting surroundings will also stimulate a mild but measurable increase in pulse rate and blood pressure. Obviously this response does not depend on the afferent limb of sympathetic reflex arc.
the sympathetic reflex arc and must be mediated by cortical-hypothalamic mechanisms.

If the response to the Valsalva maneuver is abnormal and the response to the cold pressor test is normal, the lesion is probably in the baroreceptors or their afferent nerves; such a defect has been found in diabetic and tabetic patients and is common in many neuropathies. A failure of the pulse rate and blood pressure to rise during mental arithmetic coupled with an abnormal Valsalva maneuver suggests a defect in the central or peripheral efferent sympathetic pathways.

**Tests of Sudomotor Function**  The integrity of sympathetic efferent pathways can be assessed further by tests of sudomotor activity. There are several of these, all somewhat cumbersome and used mainly in specialized autonomic testing laboratories; furthermore, most of them cannot differentiate central from peripheral causes of anhidrosis. The simplest tests involve weighing sweat after it is absorbed by small squares of filter paper. Also, powdered charcoal dusted on the skin will cling to moist areas and not to dry ones.

In the **sympathetic or galvanic skin-resistance** test, a set of electrodes placed on the skin measures the resistance to the passage of a weak current through the skin; in all likelihood, the change in electrical potential is the result of an ionic current within the sweat glands, not simply an increase in sweating that lowers skin resistance. This method can be used to outline an area of reduced sweating due to a peripheral nerve lesion, since the response depends on sympathetic activation of sweat glands (Gutrecht). The starchiodine test or use of a color indicator such as quinizarin (gray when dry, purple when wet) and the more recently introduced plastic or silicon method are other acceptable procedures.

A more quantitative and reproducible examination of postganglionic sudomotor function, termed QSART, has been developed and studied extensively by Low. It is essentially a test of distal sympathetic axonal integrity utilizing the local axon reflex. A 10% solution of acetylcholine is iontophoresed onto the skin using 2 mA for 5 min. Sweat output is recorded in the adjacent skin by sophisticated circular cells that detect the sweat water. The forearm, proximal leg, distal leg, and foot have been chosen as standardized recording sites. By this test, Low has been able to define patterns of absent or delayed sweating that signify postganglionic sympathetic failure in small-fiber neuropathies and excessive sweating or reduced latency in response, as is seen in reflex sympathetic dystrophy. This is the preferred method of studying sweating and the function of distal sympathetic fibers, but its technical complexity makes it available only in specially equipped laboratories.

**Lacrimal Function**  **Tearing** can be estimated roughly by inserting one end of a 5-mm-wide and 25-mm-long strip of thin filter paper into the lower conjunctival sac while the other end hangs over the edge of the lower lid (the Schirmer test). The tears wet the strip of filter paper, producing a moisture front. After 5 min, the moistened area extends for a length of approximately 15 mm in normal persons. An extent of less than 10 mm is suggestive of hypolacrinia. This test is used mainly to detect the dry eyes (keratoconjunctivitis sicca) of the Sjögren syndrome, but it may also be helpful in fully studying various autonomic neuropathies.

**Tests of Bladder, Gastrointestinal, and Penile Erectile Function**  **Bladder function** is best assessed by the cystometrogram, which measures intravesicular pressure as a function of the volume of saline solution permitted to flow by gravity into the bladder. The rise of pressure as 300 mL of fluid is allowed to flow gradually into the bladder, the emptying contractions of the detrusor, and the volume at which the patient reports a sensation of bladder fullness can be recorded by a manometer. (A detailed account of cystometric techniques can be found in the monograph of Krane and Siroky.) A simple way of determining bladder atony (prostatic obstruction and overdistention having been excluded) is to measure the residual urine (by catheterization of the bladder) immediately after voluntary voiding or to estimate its volume by intravenous myelography or ultrasound imaging.

**Disorders of gastrointestinal motility** are readily demonstrated radiologically. In dysautonomic states, a barium swallow may disclose a number of abnormalities, includingatomic dilatation of the esophagus, gastric atony and distention, delayed gastric emptying time, and a characteristic small bowel pattern consisting of an increase in frequency and amplitude of peristaltic waves and rapid intestinal transit. A barium enema may demonstrate colonic distention and a decrease in propulsive activity. Sophisticated manometric techniques are now available for the measurement of gastrointestinal motility, especially in the esophagus (see Low et al).

Nocturnal penile tumescence is recorded in many sleep laboratories and may be used as an ancillary test of sacral autonomic (parasympathetic) innervation.

**Pharmacologic Tests of Autonomic Function**  The topical application of pharmacologic agents is particularly useful in evaluating pupillary denervation. Part of the rationale behind these special tests is “Cannon’s law,” or the phenomenon of denervation hypersensitivity, in which an effector organ, 2 to 3 weeks after denervation, becomes hypersensitive to its particular neurotransmitter substance and related drugs.

The instillation of a 1:1000 solution of epinephrine into the conjunctival sac has no effect on the normal pupil but will cause the sympathetically denervated pupil to dilate (3 drops instilled three times at 1-min intervals). The pupillary size is checked after 15, 30, and 45 min. As a rule, hypersensitivity to epinephrine is greater with lesions of postganglionic fibers than of preganglionic fibers. If denervation is incomplete, the hypersensitivity phenomenon may not be demonstrable. Also, in lesions that involve central sympathetic pathways, the pupil rarely reacts to this test.

More reliable as a test of sympathetic denervation is the topical application into the conjunctival sac of a 4 to 10% cocaine solution that potentiates the effects of NE by preventing its uptake. The test should be carried out as described above. A normal response to cocaine consists of pupillary dilatation. In sympathetic denervation caused by lesions of the post- or preganglionic fibers, no change in pupillary size occurs, since no transmitter substance is available. The reason for lack of response in chronic preganglionic lesions is presumed to be a depletion of NE in the postganglionic fibers. In cases of central sympathetic lesions, slight mydriasis occurs.

These and other pharmacologic methods of evaluating pupillary disturbances are considered more fully in Chap. 14 and are outlined in Fig. 14-8.

**Cutaneous Flare Response**  The intracutaneous injection of 0.05 mL of 1:1000 histamine phosphate normally causes a 1-cm wheal after 5 to 10 min. This is surrounded by a narrow red areola, and it, in turn, by an erythematous flare that extends 1 to 3 cm beyond the border of the wheal. A similar “triple response” follows the
release of histamine into the skin as the result of a scratch. It can be elicited in sensitive individuals by scratching the skin (dermatographia). The wheal and the deeply colored red areola are caused by the direct action of histamine on blood vessels, while the flare depends upon the integrity of the axon reflex, in which antidromic stimulation of small sensory C fibers results in the release by the same fibers of vasoactive substances such as histamine. In familial dysautonomia, the flare response to histamine and to scratch is absent. It may also be absent in peripheral neuropathies that involve sympathetic nerves (e.g., diabetes, alcoholic-nutritional disease, Guillain-Barré disease, amyloidosis, porphyria, etc.). The quantitative sudomotor response to topical acetylcholine, described above, is preferred for its sensitivity and accuracy but requires special equipment.

**Pressor Infusion and Other Direct Cardiovascular Tests**

The infusion of NE causes a rise in blood pressure, which is usually more pronounced for a given infusion rate in dysautonomic states than it is with normal subjects. In many instances, e.g., the Guillain-Barré syndrome, the excessive rise in blood pressure is thought to be more a result of inadequate muting of the hypertension by baroreceptors than it is a reflection of true denervation hypersensitivity, i.e., it reflects dysfunction of the afferent limb of the reflex arc. In patients with familial dysautonomia, the infusion of NE also produces erythematous blotching of the skin, like that which may occur under emotional stress, probably representing an exaggerated response to endogenous NE.

The infusion of angiotensin II into patients with idiopathic orthostatic hypotension also causes an exaggerated blood pressure response. A similar response to methacholine and NE has been interpreted as a denervation hypersensitivity to neurotransmitter or related substances. A different mechanism must be invoked for the blood pressure response induced by angiotensin; perhaps it is due to defective baroreceptor function.

The integrity of autonomic innervation of the heart can be evaluated by the intramuscular injection of atropine, ephedrine, or neostigmine while the heart rate is monitored. Normally, the intramuscular injection of 0.8 mg of atropine causes a parasympathetic block and a withdrawal of vagal tone. No such change occurs in cases of parasympathetic (vagal) denervation of the heart, the most common such conditions being diabetes and the Guillain-Barré syndrome and the most dramatic being the brain death state, in which there is no longer any tonic vagal activity to be abducted by atropine.

Microchemical methods are available for the measurement of NE and dopamine β-hydroxylase in the serum. Normally, when a person changes from a recumbent to a standing position, the serum NE level rises two- or threefold. In patients with central and peripheral autonomic failure, there is little or no elevation on standing or with exercise. The dopamine β-hydroxylase enzyme is deficient in patients with a rare form of sympathectic dysautonomia.

In summary, the noninvasive tests listed in Table 26-1 and described above are quite adequate for the clinical testing of autonomic function. Low has emphasized that the most informative tests are those that are quantitative and have been standardized and validated in patients with both mild and severe autonomic disturbances. At the bedside, the most convenient ones are measurement of orthostatic pulse and blood pressure changes, blood pressure response to the Valsalva maneuver, estimation of pulse changes with deep breathing, pupillary responses to light and dark, and a rough estimate of sweating of the palms and soles. The results of these tests and the clinical situation will determine whether further testing is needed.

**CLINICAL DISORDERS OF THE AUTONOMIC NERVOUS SYSTEM**

**Acute Autonomic Paralysis (Dysautonomic Polyneuropathy; Pure Pandysautonomia)**

Since this condition was first reported by Young and colleagues in 1975, many more cases in both adults and children have been placed on record. Over a period of a week or a few weeks, the patient develops some combination of anhidrosis, orthostatic hypotension, paroxysms of pupillary reflexes, loss of lacrimation and salivation, impotence, impaired bladder and bowel function (urinary retention, postprandial bloating, and ileus or constipation), and loss of certain pilomotor and vasomotor responses in the skin (flushing and heat intolerance). Somatosensory and reflex function are usually spared. Severe fatigue is a prominent complaint in most patients, and abdominal pain and vomiting in others. A few develop sleep apnea or the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), leading to hyponatremia. The cerebrospinal fluid (CSF) protein is normal or slightly increased.

Clinical and laboratory findings indicate that both the sympathetic and parasympathetic parts of the autonomic nervous system are affected, mainly at the postganglionic level. Somatosensory and motor nerve fibers appear to be spared or are affected only to a slight extent, although many patients complain of paresthesias, and tendon reflexes are frequently lost. In one of the patients described by Low and colleagues, there was physiologic and morphologic (sural biopsy) evidence of loss of small myelinated and unmyelinated somatic fibers and foci of epineurial mononuclear cells; in other cases, sural nerve fiber counts have been normal; and in an autopsied case, in which there had also been sensory loss, there was lymphohypertrophic infiltration in sensory and autonomic nerves (Fagius et al). The original patient described by Young and colleagues and most of the other patients reported with pure dysautonomia are said to have recovered completely or almost so within several months, but some of our patients have been left with disordered gastrointestinal and sexual functions. In addition to this idiopathic form of autonomic paralysis, some cases are postinfectious, and there is a similar but rare paraneoplastic form (page 586). Antibodies against ganglionic acetylcholine receptors have been found in half of idiopathic cases and one-quarter of paraneoplastic cases (Vernino et al).

Some of the children with this disease and a few adults have had a predominantly cholinergic dysautonomia with pain and dysesthesias (Kirby et al). There is little or no postural hypotension, and the course has been more chronic than that in the complete dysautonomia described above.

In view of the occurrence of identical autonomic disturbances in the Guillain-Barré syndrome and the high incidence of minor degrees of weakness, reflex loss, CSF protein elevation, and especially paresthesias in dysautonomic polyneuropathy, it is likely that the last of these disorders is also an immune polyneuropathy affecting the autonomic fibers within peripheral nerves, in many ways comparable to the Guillain-Barré syndrome. The aforementioned autopsy findings reported by Fagius and coworkers support such a relationship. In animals, autonomic paralysis has been produced by injection of extracts of sympathetic ganglia and Freund's
adjuvant (Appenzeller et al), similar to the experimental immune neuritis that is considered as an animal model of the Guillain-Barré syndrome.

An acquired form of orthostatic intolerance, referred to as sympathotonic orthostatic hypotension (Polinsky et al), may represent another variant or partial form of autonomic paralysis. In this syndrome, unlike the common forms of orthostatic hypotension (see below), the fall in blood pressure is accompanied by tachycardia. Hoeldtke and colleagues, who described four such patients, found that the vasomotor reflexes and NE production were normal; these investigators were inclined to attribute the disorder to a process affecting lower thoracic and lumbar sympathetic neurons. Its relationship to the similarly indistinct entity of postural orthostatic tachycardia syndrome and to the orthostatic intolerance associated with the chronic fatigue syndrome is uncertain, but asthenia is a feature common to all of them. Indeed, similar syndromes in the past have been called neurocirculatory asthenia ("soldiers’ heart," Da Costa syndrome; see Chap. 24). We are inclined to view those so-called orthostatic intolerance syndromes as part of the asthenia-anxiety disorders. The autonomic changes may represent sympathetic overactivity in susceptible individuals.

Lambert-Eaton Myasthenic Syndrome One of the characteristic features of the fully developed Lambert-Eaton myasthenic syndrome, which is discussed more fully on page 1259, is a dysautonomia, characterized by dryness of the mouth, impotence, difficulty in starting the urinary stream, and constipation. Presumably, circulating antibodies interfere with the release of acetylcholine (Ach) at both muscarinic and nicotinic sites.

Primary Autonomic Failure (PAF), Idiopathic Orthostatic Hypotension (IOH)

This clinical state is now known to be caused by at least two conditions. One is a degenerative disease of middle and late adult life, first described by Bradbury and Eggleston in 1925 and designated by them as idiopathic orthostatic hypotension. This term is not entirely apt, since it emphasizes only one feature of the autonomic failure and neglects the disturbances of sweating and of bladder and sexual functions, which are usually associated. In this disorder, the lesions are said to involve mainly the postganglionic sympathetic neurons (Petito and Black); the parasympathetic system is relatively spared and the CNS is uninvolved. In the second more common disorder, described by Shy and Drager, the preganglionic lateral horn neurons of the thoracic spinal segments degenerate; these changes are responsible for the orthostatic hypotension. Later, signs of basal ganglionic or cerebellar disease or both are usually added, in which case the disorder is called multiple system atrophy (an unfortunate descriptive term in our view, as expressed below and in Chaps. 18 and 39). In both types of orthostatic hypotension, anhidrosis, impotence, and atony of the bladder may be conjoined, but orthostatic fainting is the main problem.

The clinical differentiation of these two types of orthostatic hypotension depends largely on the appearance, with time, of associated CNS signs as described below. The distinction between the postganglionic and the central preganglionic types of disease is also based on pharmacologic and neurophysiologic evidence, but it must be emphasized that the results of these tests do not always conform to clinical experience. Nonetheless, Cohen and associates, who studied the postganglionic sudomotor and vasomotor functions of 62 patients with idiopathic orthostatic hypotension, found that the signs of postganglionic denervation were uncommon in patients classified as having the central type.

In the postganglionic type of autonomic failure, plasma levels of NE are subnormal while the patient is recumbent because of failure of the damaged nerve terminals to synthesize or release catecholamines. When the patient stands, the NE levels do not rise, as they do in a normal person. Also, in this type, there is denervation hypersensitivity to infused NE. In the central preganglionic (Shy-Drager) type, the resting NE levels in the plasma are normal, but again, on standing, there is no rise, and the response to exogenously administered NE is normal. In both types, the plasma levels of dopamine β-hydroxylase, the enzyme that converts dopamine to NE, are subnormal (Ziegler et al). The use of these neurochemical tests in clinical practice is difficult and the data in the literature are inconsistent. Low’s monograph should be consulted for procedural details.

Pathologic studies have disclosed the central type of autonomic failure to be somewhat heterogeneous. Oppenheimer, who collected all the reported central cases with complete autopsies, found that they fell into two groups: (1) that which was designated by Adams as striatongiral degeneration or, later, Shy-Drager syndrome, where autonomic failure was associated with a parkinsonian syndrome and often with the presence of cytoplasmic inclusions in sympathetic neurons, and (2) another with involvement of the striatum, cerebellum, pons, and medulla but without inclusions, formerly designated olivopontocerebellar degeneration (there are now reported to be glial and neuronal cytoplasmic inclusions in all these cases). Both conditions are now loosely referred to as multiple system atrophy, as discussed in Chap. 39. In both groups, the autonomic failure is attributable to degeneration of lateral horn cells of the thoracic cord. There is also a degeneration of nerve cells in the vagal nuclei as well as nuclei of the tractus solitarius, locus ceruleus, and sacral autonomic nuclei, accounting for laryngeal abductor weakness (laryngeal paralysis and stridor are features in some cases), incontinence, and impotence. NE and dopamine are depleted in the hypothalamus (Spokes et al). The sympathetic ganglia have been normal, an exception being the case of Rajput and Rozdilsky, in which most of the ganglion cells had degenerated. (In Parkinson disease, where fainting is sometimes a problem, Lewy bodies are found in degenerating sympathetic ganglion cells.)

Treatment of orthostatic hypotension consists of having the patient sleep with the head of the bed elevated, administering mineralocorticoid medications such as fludrocortisone acetate (Florinef) 0.1 mg twice daily, or midodrine starting at 2.5 mg q 4 h, slowly raising the dose to 5 mg q 4 h, and using elastic stockings that compress the veins of the legs and lower abdomen.

Peripheral Neuropathy with Secondary Orthostatic Hypotension

Impairment of autonomic function, of which orthostatic hypotension is the most serious feature, may occur as part of the more common acute or chronic peripheral neuropathies (e.g., diabetic, alcoholic-nutritional, amyloid, Guillain-Barré, heavy metal—toxic, and porphyric). Disease of the peripheral nervous system may affect the circulation in two ways: the nerves from baroreceptors may be affected, interrupting normal homeostatic reflexes on the afferent side, or postganglionic efferent sympathetic fibers may be involved in the spinal nerves. The severity of the autonomic failure need not parallel the degree of motor weakness. An additional feature of the acute dysautonomias is a tendency to develop hypona-
tremia, presumably as a result of dysfunction of afferent fibers from aortic arch volume receptors, which elicits a release of vasopressin. These same stretch baroreceptors are implicated in the intermittent hypertension that sometimes complicates these acute neuropathies.

Of particular importance is the autonomic disorder that accompanies diabetic neuropathy. It presents as impotence, constipation, or diarrhea (especially at night), hypotonia of the bladder, gastroparesis, and orthostatic hypotension, in some combination. There are invariably signs of a sensory polyneuropathy, consisting of a distal loss of vibratory and thermal-pain sensation and reduced or lost ankle reflexes; but again, the severity of affection of the two systems of nerve fibers may not be parallel. The pupils are often small and the amplitude of constriction to light is reduced (Argyll-Robertson pupils); this has been attributed to involvement of the ciliary ganglia. The pathologic basis of the other features has been difficult to assess because of the frequency of artifact in the sympathetic ganglia in autopsy material. Duchen and coworkers attributed the autonomic disorder to vacuolization of sympathetic ganglionic neurons, cell necrosis and inflammation, loss of myelinated fibers in the vagi and white rami communicantes, and loss of lateral horn cells in the spinal cord. They believe the latter changes to be secondary.

Another polyneuropathy with unusually prominent dysautonomia is that due to amyloidosis. Extensive loss of pain and thermal sensation is usually present; other forms of sensation may also be reduced to a lesser degree. Motor function is much less altered. Sympathetic function is more affected than parasympathetic. Iris-dopleria (pupillary paralysis) and disturbances of other smooth muscle and glandular functions are variable. Diabetic and amyloid polyneuropathy are further described in Chap. 46.

Both the primary and secondary types of orthostatic hypotension are also discussed in connection with syncope in Chap. 18.

**Autonomic Neuropathy in Infants and Children (Riley-Day Syndrome) and Other Inherited Dysautonomias**

This is a familial disease of children, inherited as an autosomal recessive trait. The main symptoms are postural hypotension and lability of blood pressure, faulty regulation of temperature, diminished hearing, hyperhidrosis, blotchiness of the skin, insensitivity to pain, emotional lability, and cyclic vomiting. The tendon reflexes are hypoactive and mild slowing of motor nerve conduction velocities is common. There is denervation sensitivity of the pupils and other structures. The main pathologic feature is a deficiency of neurons in the superior cervical ganglia and in the lateral horns of the spinal cord. Also, the number of unmyelinated nerve fibers in the sural nerve is greatly decreased according to Aguayo and to Dyck and their colleagues (see also page 1159). It is likely that this disease represents a failure of embryologic migration or formation of the first- and second-order sympathetic neurons. It is now known that this defect is the result of a mutation in the gene coding for a protein that is associated with the transcription regulator, Ikappa B (Anderson et al).

Autonomic symptoms may also be a prominent feature of the small-fiber neuropathy of Fabry disease (α-galactosidase deficiency) as a result of the accumulation of ceramide in hypothalamic and intermediolateral column neurons (see pages 839 and 1159).

Another inherited form of peripheral dysautonomia is characterized by severe pain in the feet on exercise and an autosomal dominant pattern of inheritance (Robinson and colleagues.) Stabbing pains in the feet were increased by bending, crouching, and kneeling. There was no sweat response to intradermal injection of 1% ACh and no autonomic fibers were found in punch biopsies of the skin. Fabry disease was excluded.

**Autonomic Failure in the Elderly**

Orthostatic hypotension is prevalent in the elderly, so much so that norms of blood pressure and pulse changes have been difficult to establish. Caird and coworkers reported that among individuals who were more than 65 years of age and living at home, 24 percent had a fall of systolic blood pressure on standing of 20 mmHg; 9 percent had a fall of 30 mmHg; and 5 percent, a fall of 40 mmHg. An increased frequency of thermoregulatory impairment has been documented as well. The elderly are also more liable to develop hypothermia and, when exposed to high ambient temperature, to hyperthermia. Loss of sweating of the lower parts of the body and increased sweating of the head and arms probably reflect a senile neuropathy or neuronopathy. The number of sensory ganglion cells decreases with age (Castro). Impotence and incontinence also increase with age, but these, of course, may be due to a number of processes besides autonomic failure.

It is of interest that the idiopathic type of small fiber neuropathy that occurs predominantly in elderly women (“burning hands and feet” syndrome) has no associated autonomic features (see Chap. 46).

**Horner (Oculosympathetic) and Stellate Ganglion Syndromes**

 Interruption of preganglionic sympathetic fibers at any point along the internal carotid arteries or a lesion of the superior cervical ganglion results in miosis, dropping of the eyelid, and abolition of sweating over one side of the face; this constellation is the Horner, or more properly, Bernard-Horner syndrome (see also page 242). The same syndrome in less obvious form may be caused by interruption of the preganglionic fibers at any point between their origin in the intermediolateral cell column of the C8-T2 spinal segments and the superior cervical ganglion or by interruption of the descending, uncrossed hypothalamospinal pathway in the tegmentum of the brainstem or cervical cord. The common causes are neoplastic or inflammatory involvement of the cervical lymph nodes or proximal part of the brachial plexus, surgical and other types of trauma to cervical structures (e.g., jugular venous catheters), carotid artery dissection, syringomyelic or traumatic lesions of the first and second thoracic spinal segments, and infarcts or other lesions of the lateral part of the medulla (Wallenberg syndrome). There is also an idiopathic variety that is in some cases hereditary. If a Horner syndrome develops early in life, the iris on the affected side fails to become pigmented and remains blue or mottled gray-brown (het erochromia iridis).

A lesion of the stellate ganglion, e.g., compression by a tumor arising from the superior sulcus of the lung, produces the interesting combination of a Horner syndrome and paralysis of sympathetic reflexes in the limb (the hand and arm are dry and warm). With preganglionic lesions, facial flushing may develop on the side of the sympathetic disorder; this is brought on in some instances by exercise (harlequin effect).

Keane has provided data as to the relative frequency of the lesions causing oculosympathetic (Horner) paralysis. In 100 suc-
censive cases, 63 were of central type due to brainstem strokes, 21
were preganglionic from trauma or tumors of the neck, 13 were
postganglionic due to miscellaneous causes, and in 3 cases the lo-
calization could not be determined (see Chap. 14 for further dis-
cussion).

The pupillary disturbances associated with oculomotor nerve
lesions, the Adie pupil, and other parasympathetic and sympathetic
abnormalities of pupillary function are considered fully in Chap.
14. The combination of segmental anhidrosis and an Adie pupil is
sometimes referred to as the Ross syndrome; it may be abrupt in
onset and idiopathic or may follow a viral infection.

**Sympathetic and Parasympathetic Paralysis in Tetraplegia and Paraplegia**

Lesions of the C4 or C5 segments of the spinal cord, if complete,
will interrupt suprasegmental control of both the sympathetic and
sacral parasympathetic nervous systems. Much the same effect is
observed with lesions of the upper thoracic cord (above T6). Lower
thoracic lesions leave much of the descending sympathetic outflow
intact, only the descending sacral parasympathetic control being
interrupted. Traumatic necrosis of the spinal cord is the usual cause
of these states, but they may be due as well to infarction, certain
forms of myelitis, and tumors.

As discussed in greater detail in Chap. 44, the initial effect of
an acute cervical cord transection is abolition of all sensorimotor,
reflex, and autonomic functions of the isolated spinal cord. The
autonomic changes include hypotension, loss of sweating and
piloerection, paralytic ileus and gastric atony, and paralysis of the
bladder. Plasma epinephrine and NE are reduced. This state, known
as spinal shock, lasts for several weeks. The basic mechanisms are
not known, but changes in neurotransmitters (catecholamines, en-
dorphins, substance P, and 5-hydroxytryptamine) are under inves-
tigation.

After spinal shock dissipates, sympathetic and parasympa-
thetic functions return, since the afferent and efferent autonomic
connections within the isolated segments of the spinal cord are
intact, although no longer under the control of higher centers. With
cervical cord lesions, there is a loss of the sympathetically medi-
dated cardiovascular changes in response to stimuli reaching the
medulla. However, cutaneous stimuli (pinprick or cold) in seg-
ments of the body below the transection will raise the blood pres-
sure. However, a fall in blood pressure is not compensated by
sympathetic vasoconstriction. Hence tetraplegics are almost oblig-
atory prone to orthostatic hypotension. Pinching the skin below
the lesion causes gooseflesh in adjacent segments. Heating the body
results in flushing and sweating over the face and neck but not the
trunk and legs. Bladder and bowel, including their sphincters,
which are at first flaccid, become automatic as spinal reflex control
returns. There may be reflex penile erection or priapism and even
ejaculation. With lesions in the upper thoracic cord, similar but
lesser degrees of labile blood pressure are seen; in several of our
patients with destructive myelitis, a viral infection of fever brought
out episodes of a drop in blood pressure to approximately 80/60
mm Hg and a subsequent rapid rise to 190/110 mmHg.

After a time the tetraplegic may develop a mass reflex (page
1052), in which flexor spasms of the legs and involuntary em-
tying of the bladder are associated with a marked rise in blood
pressure, bradycardia, and sweating and pilomotor reactions in
parts below the cervical segments (autonomic dysreflexia). These
reactions may also be evoked by pinprick, passive movement, con-
tactual stimuli of the limbs and abdomen, and pressure on the blad-
der. An exaggerated vasopressor reaction also occurs in response
to injected NE. In such attacks, the patient experiences paresthesias
of the neck, shoulders, and arms; tightness in the chest and dyspnea;
pupillary dilatation; pallor followed by flushing of the face; sen-
sation of fullness in the head and ears; and a throbbing headache.
Plasma NE and dopamine rise slowly during the autonomic dis-
charge. When such an attack is severe and prolonged, myocardial
infarction, seizures, and visual defects have been observed. Clon-
idine, up to 0.2 mg three times daily, has been useful in preventing
the hypertensive crises.

**Acute Autonomic Crises (Sympathetic Storm)**

Several toxic and pharmacologic agents such as cocaine and phen-
ylpropanolamine are capable of producing abrupt overactivity of
the sympathetic and parasympathetic nervous systems—severe
hypertension and mydriasis coupled with signs of CNS excita-
tion, sometimes including seizures. Tricyclic antidepressants in ex-
cessive doses are also known to produce autonomic effects, but in
this case there is cholinergic blockade, leading to dryness of the
mouth, flushing, absent sweating, and mydriasis. The main concern
with tricyclic antidepressant overdose is the development of a
ventricular arhythmia, also on an autonomic basis, presaged by
prolongation of the QT interval on the ECG. Poisoning with or-
ganophosphate insecticides (e.g., Parathion), which have anticho-
linesterase effects, causes a combination of parasympathetic over-
activity and motor paralysis (see page 1037). A severe degree of
autonomic disturbance, involving both postganglionic sympathetic
and parasympathetic function, is produced by ingestion of the ro-
denticide N-3-pyridylmethyl-N'p-nitrophenylurea (PNU, Vacor).
The exaggerated sympathetic state that accompanies tetanus—
manifest by diaphoresis, mydriasis, and labile or sustained hyper-
tension—has been attributed to circulating catecholamines.

Among the most dramatic syndromes of unopposed sympa-
thetic-adrenal medullary hyperactivity occur in the context of se-
vere head injury and with hypertensive cerebral hemorrhage. Three
mechanisms of the hypersympathetic state are observed at
different times after the injury or cerebral hemorrhage: an out-
pouring of adrenal catecholamines at the time of acute hypertension and tachycardia; a brainstem-mediated vasopressor reaction (Cushing response, described below); and a later
phenomenon, consisting of extreme hypertension, profuse diapho-
resis, and pupillary dilation, usually arising during episodes of se-
veral minutes duration of rigid extensor posturing (the “diencephalic
autonomic seizures” of Penfield, described below and in Chap. 35
in relation to head injury).

Regarding the first type of sympathetic response, experimental
evidence suggests that nuclei in the caudal medullary reticular for-
mation (reticularis gigantocellularis and parvocellularis) can pre-
cipitate severe hypertensive reactions. These nuclear centers are
tonically inhibited by the nucleus of the tractus solitarius (NTS),
which receives afferent input from arterial baroreceptors and che-
moreceptors. Bilateral lesions of the NTS therefore produce ex-
treme elevations in blood pressure, and this abrupt rise plays a role
in the genesis of “neurogenic” pulmonary edema (see page 488).
These sympathetically mediated effects are eliminated by section-
ing of the cervical spinal cord and by alpha-adrenergic blockade.

The Cushing response, reflex, or “reaction,” as Cushing de-
scribed it, occurs as a result of an abrupt increase in intracranial
pressure. It consists of a triad of hypertension, bradycardia, and slow, irregular breathing elicited by the stimulation of mechanically sensitive regions in the paramedian caudal medulla (Hoff and Reis). Similar pressure-sensitive areas in the upper cervical spinal cord are also implicated in the Cushing response when intraspinal pressure is raised abruptly; a ventral medullary vasodepressor area that acts in the opposite manner has been found in animals. The proximate cause of the Cushing response is a mechanical distortion of the lower brainstem, either from a mass in the posterior fossa or, more often, from a large mass in one of the hemispheres or a subarachnoid hemorrhage causing a transmitted pressure that elevates the pressure within the fourth ventricle. Often, only the hypertensive component of the reaction occurs, with the systolic blood pressure reaching levels of 200 mmHg, spurringly suggesting the presence of a pheochromocytoma or renal artery stenosis.

In our experience, the most severe instances of this type of centrally provoked hypertensive syndrome have occurred in children with cerebellar tumors who presented with headache and extreme systolic hypertension. Difficulty may arise in differentiating this response from hypertensive encephalopathy, especially from cases that derive from renovascular hypertension, which may likewise be accompanied by headache and papilledema. In making a differentiation between these two, it is useful to note that hypertensive encephalopathy is associated with a tachycardia or normal heart rate and that systolic blood pressure levels above 210 mmHg are attained only rarely in the Cushing response.

In relation to the third type of sympathetic hyperactivity, Penfield described paroxysms of hypertension, intense diaphoresis, flushed skin, and mydriasis in comatose patients and attributed them to epilepsy (diencephalic seizures), although his original patient had a tumor obstructing the foramen of Munro. Many similar types of attacks have been described, additional features being a slight rise in temperature just prior to the paroxysm, cyclic respiations, and shivering. Often the bedsheets become soaked and the patient’s forehead is covered by beads of sweat. Most patients who exhibit such paroxysms are decorticate from traumatic lesions of the deep cerebral white matter or from acute hydrocephalus (the likely explanation of Penfield’s cases); in any case, they are clearly not epileptic. We have conceptualized these attacks as the result of the removal of inhibitory influences on the hypothalamus, creating, in effect, a hypersensitive decorticated autonomic nervous system. The condition is perhaps analogous to overactivity of the extensor and opisthotonic posturing mechanisms that appear with little provocation in the same clinical settings. Morphine and bromocriptine have been helpful in suppressing but not eliminating the attacks, and beta-adrenergic blockers reduce the hypertension and tachycardia.

During episodes of intense sympathetic discharge of any type, there are alterations in the ECG, mainly in the ST segments and T waves; in extreme cases, evidence of myocardial damage can be observed. The role of direct sympathetic innervation of the heart in producing these myocardial abnormalities is unclear, but in the cases of subarachnoid hemorrhage and traumatic brain injury, the surge in circulating NE and cortisol is postulated as the cause. A similar hyperadrenergic mechanism has been proposed to explain sudden death from fright, asthma, status epilepticus, and cocaine overdose. Investigations by Schoebel and colleagues have suggested that sustained sympathetic overactivity is responsible for the hypertension of pre-eclampsia, which may be considered in some ways as a dysautonomic state. Further information on these topics is contained in the reviews by Samuels and by Ropper.

A role has also been inferred for the ventrolateral medullary pressor centers in the maintenance of essential hypertension. Geiger and colleagues removed a looped branch of the posteroinferior cerebellar artery that had been apposed to the ventral surface of the medulla in 8 patients who had intractable essential hypertension; they found that 7 improved. Vascular decompression of cranial nerves has proved to be a credible therapeutic measure for hemifacial spasm and some cases of vertigo and trigeminal neuralgia, as discussed in Chap. 4, but the notion of vascular compression of the ventral medulla as a valid mechanism for essential hypertension requires confirmation.

The Effects of Thoracolumbar Sympathectomy Surgical resection of the thoracolumbar sympathetic trunk, widely used in the 1940s in the treatment of hypertension, has provided the clinician with the clearest examples of extensive injury to the peripheral sympathetic nervous system, though a similar defect had long been suspected in one type of primary orthostatic hypotension (see above). In general, bilateral thoracolumbar sympathectomy results in surprisingly few disturbances. Aside from loss of sweating over the denervated areas of the body, the most pronounced abnormality is an impairment of vasomotor reflexes. In the upright posture, faintness and syncope are frequent because of pooling of blood in the splanchnic bed and lower extremities; although the blood pressure may fall steadily to shock levels, there is little or no pallor, nausea, vomiting, or sweating—the usual accompaniments of syncope. Bladder, bowel, and sexual function are preserved, though semen is sometimes ejaculated into the posterior urethra and bladder. No consistent abnormalities of renal or hepatic function have been found.

Disorders of Sweating

Hyperhidrosis results from overactivity of sudomotor nerve fibers under a variety of conditions. It may occur as an initial excitatory phase of certain peripheral neuropathies (e.g., due to arsenic or thallium) and be followed by anhidrosis; it is one aspect of the sympathetic reflex dystrophy pain syndromes (see pages 121 and 189). Disorders of small nerve fibers, which enhance adrenergic responses, may also be associated with excessive sweating. This is also observed as a localized effect in painful mononeuropathies (causalgia) and diffusely in a number of painful polyneuropathies (‘‘burning foot’’ syndrome). A type of nonthermoregulatory hyperhidrosis may occur in spinal paraplegics (page 1052 and as mentioned above). Loss of sweating in one part of the body may require a compensatory increase in normal parts—for example, the excessive facial and upper truncal sweating that occurs in patients with transection of the high thoracic cord.

Localized hyperhidrosis may be a troublesome complaint in some patients. One variety, presumably of congenital origin, affects the palms. The social embarrassment of a ‘‘succulent hand’’ or a ‘‘dripping paw’’ is often intolerable. It is taken to be a sign of nervousness, though many persons with this condition disclaim all other neurotic symptoms. Cold, clammy hands are common in individuals with anxiety, and indeed this has been a useful sign in distinguishing an anxiety state from hypothyroidism, in which the hands are also moist but warm. Extirpation of T2 and T3 sympathetic ganglia relieves the more severe cases of palmar sweating; a Horner syndrome does not develop if the T1 ganglion is left intact. In other cases, the hyperhidrosis affects mainly the feet.

Anhidrosis in restricted skin areas is a frequent and useful
finding in peripheral nerve disease. It is due to the interruption of the postganglionic sympathetic fibers, and its boundaries can be mapped by means of the sweat tests described earlier in the chapter. The loss of sweating corresponds to the area of sensory loss. In contrast, sweating is not affected in spinal root disease because there is much intersegmental mixing of the preganglionic axons once they enter the sympathetic chain.

A postinfectious anhidrosis syndrome has been described, sometimes accompanied by mild orthostatic hypotension. The process is probably a limited form of the “pure pandysautonomia” described earlier. Corticosteroids are said to be beneficial, but we have not found them so.

Raynaud Syndrome This disorder, characterized by episodic, painful blanching of the fingers and presumably caused by digital artery spasm, was first described by Raynaud in 1862. The classic appearance is of a triphasic sequence of color change of pallor, cyanosis, and subsequent rubor of the affected fingers or toes. But about one-third of such patients have no cyanosis. The episodes are brought on by cold or emotional stress and are usually followed by redness on rewarming. Numbness, paresthesias, and burning often accompany the color changes. It is a disease of early onset, the mean age in idiopathic cases being 14, and it occurs in a number of clinical settings.

Although most cases are idiopathic, in about half there is an associated connective tissue disease, scleroderma being the main one (Porter et al.). In these patients, mostly women with the onset of digital symptoms after age 30, the Raynaud syndrome may antedate the emergence of scleroderma or another rheumatologic autoimmune disorder by many years; such disease usually develops within 2 years. In a small group, predominantly men, the syndrome is induced by local trauma, such as prolonged sculling on a cold day, and particularly by vibratory injury incurred by the sustained use of a pneumatic drill or hammer (a syndrome well known in quarry workers). Obstructive arterial disease—as might occur with the thoracic outlet syndrome, vasospasm due to drugs (ergot, cytotoxic agents, cocaine), previous cold injury (frostbite), and circulating cryoglobulins—is a less common cause. Still, in 64 of 219 patients studied by Porter and coworkers, the Raynaud syndrome was classified as idiopathic, and most of our cases have been of this type. Formerly, the idiopathic form was called Raynaud disease; the type with associated disease was known as Raynaud phenomenon. The presence of distorted and proliferative capillaries in the nail bed, visible with an ophthalmoscope, has been used as a bedside aid to reveal cases of connective tissue disease.

Other processes seen by neurologists, foremost among them carpal tunnel syndrome, also cause cold sensitivity in the fingers. Attacks of digital pain and color change from vasculitis, atherosclerotic vascular occlusion, and other causes of occlusive vascular disease only superficially resemble the Raynaud phenomenon; a search for cryoprecipitable proteins in the blood is appropriate.

Irrespective of the associated disease, one of two mechanisms seems to be operative in the pathogenesis—either an arterial constriction or a decrease in the intraluminal pressure. The former, in purest form, is observed in young women on exposure to cold and aggravated by emotional stress; a decrease in intraluminal pressure is associated with arterial obstruction. Treatment is directed to the associated conditions and prevention of precipitating factors. Cervicothoracic sympathectomy has not proved to be an effective measure.

Lafferty and colleagues have pointed out that, in contrast to many areas of the body, the cutaneous nerves of the hands and feet can induce solely vasoconstrictive effects when stimulated, and dilatation is accomplished by chemical mediators. Although the sympathetic vasoconstrictive mechanism is intact, sympathectomy is usually ineffective because vasoconstriction is under control of these chemical mediators such as histamine. The vasodilating properties of the various prostaglandins have been exploited to good effect in some cases. A role for nitric oxide in causing digital vasoconstriction has been hypothesized; therefore antagonists of this substance, such as L-arginine, have been tried as therapy with some success, but other mediators of vasoconstriction, such as the peptide endothelins, have also been postulated to play a role.

Treatment Avoidance of cold exposure is an obvious strategy, as almost all affected patients have discovered by the time they see the physician. Drugs that cause vasoconstriction are interdicted (ergots, sympathomimetics, clonidine, and serotonin receptor agonists). Calcium channel blockers are most effective, nifedipine being the most widely used, in doses of 30 to 60 mg per day. Other treatments are summarized in the review by Wigley.

Erythromelalgia, first described by Weir Mitchell, is a condition of unknown cause and mechanism in which the feet and lower extremities become red and painful on exposure to warm temperatures for prolonged periods (see page 189).

Disturbances of Bladder Function

The familiar functions of the bladder and lower urinary tract—the storage and intermittent evacuation of urine—are served by three structural components: the bladder itself, the main component of which is the large detrusor (transitional type) muscle; a functional internal sphincter composed of similar muscle; and the striated external sphincter or urogenital diaphragm. The sphincters assure continence; in the male, the internal sphincter also prevents the reflux of semen from the urethra during ejaculation. For micturition to occur, the sphincters must relax, allowing the detrusor to expel urine from the bladder into the urethra. This is accomplished by a complex mechanism involving mainly the parasympathetic nervous system (the sacral peripheral nerves derived from the second, third, and fourth sacral segments of the spinal cord and their somatic sensorimotor fibers) and to a lesser extent, sympathetic fibers derived from the thorax. The brainstem “micturition centers,” with their spinal and suprasegmental connections, may contribute (Fig. 26-5).

The detrusor muscle receives motor innervation from nerve cells in the intermediolateral columns of gray matter, mainly from the third and also from the second and fourth sacral segments of the spinal cord (the “detrusor center”). These neurons give rise to preganglionic fibers that synapse in parasympathetic ganglia within the bladder wall. Short postganglionic fibers end on muscarinic acetylcholine receptors of the muscle fibers. There are also beta-adrenergic receptors in the dome of the bladder, which are activated by sympathetic fibers that arise in the intermediolateral nerve cells of T10, T11, and T12 segments. These preganglionic fibers pass via inferior splanchnic nerves to the inferior mesenteric ganglia (Figs. 26-1 and 26-4); pre- and postganglionic sympathetic axons are conveyed by the hypogastric nerve to the pelvic plexus and the bladder dome. The internal sphincter and base of the bladder (trigone), consisting of smooth muscle, are also innervated to some extent by the sympathetic fibers of the hypogastric nerves; their receptors are mainly of alpha-adrenergic type, which makes it possible to therapeutically manipulate the function of the sphincter.
with adrenergically active drugs as well as the more commonly used cholinergic ones (see further on).

The external urethral and anal sphincters are composed of striated muscle fibers. Their innervation, via the pudendal nerves, is derived from a densely packed group of somatomotor neurons (nucleus of Onuf) in the anterolateral horns of sacral segments 2, 3, and 4. Cells in the ventrolateral part of Onuf’s nucleus innervate the external urethral sphincter, and cells of the mediodorsal part innervate the anal sphincter. The muscle fibers of the sphincters respond to the nicotinic effects of ACh.

The pudendal nerves also contain afferent fibers coursing from the urethra and the external sphincter to the sacral segments of the spinal cord. These fibers convey impulses for reflex activities and, through connections with higher centers, for sensation. Some of these fibers probably course through the hypogastric plexus, as indicated by the fact that patients with complete transverse lesions of the cord as high as T12 may report vague sensations of urethral discomfort. The bladder is sensitive to pain and pressure; these senses are transmitted to higher centers along the sensory pathways described in Chaps. 8 and 9.

Unlike skeletal striated muscle, the detrusor, because of its postganglionic system, is capable of some contractions, imperfect at best, after complete destruction of the sacral segments of the spinal cord. Isolation of the sacral cord centers (transverse lesions of the cord above the sacral levels) and their peripheral nerves permits contractions of the detrusor muscle, but they still do not empty the bladder completely; patients with such lesions usually develop dyssynergia of the detrusor and external sphincter muscles (see below), indicating that coordination of these muscles must occur at supraspinal levels (Blalvins). With acute transverse lesions of the upper cord, the function of sacral segments is abolished for several weeks in the same way as the motor neurons of skeletal muscles (the state of spinal shock).

The storage of urine and the efficient emptying of the bladder is possible only when the spinal segments, together with their afferent and efferent nerve fibers, are connected with the so-called micturition centers in the pontomesencephalic tegmentum. In experimental animals, this center (or centers) lies within or adjacent to the locus ceruleus. A medial region triggers micturition, while a lateral area seems more important for continence. These centers receive afferent impulses from the sacral cord segments; their efferent fibers course downward via the reticulospinal tracts in the lateral funiculi of the spinal cord and activate cells in the nucleus of Onuf as well as in the intermediolateral cell groups of the sacral segments (Holstege and Tan). In cats, the pontomesencephalic centers receive descending fibers from anteromedial parts of the frontal cortex, thalamus, hypothalamus, and cerebellum, but the brainstem centers and their descending pathways have not been precisely defined in humans. Other fibers, from the motor cortex, descend with the corticospinal fibers to the anterior horn cells of the sacral cord and innervate the external sphincter. According to Ruch, the descending pathways from the midbrain tegmentum are inhibitory and those from the pontine tegmentum and posterior hypothalamus are facilitatory. The pathway that descends with the corticospinal tract from the motor cortex is inhibitory. Thus the net effect of lesions in the brain and spinal cord on the micturition reflex, at least in animals, may be either inhibitory or facilitatory (DeGroat).

Almost all of this information has been inferred from animal experiments; there is little human pathologic material to corroborate the role of central nuclei and cortex in bladder control. What information is available is reviewed extensively by Fowler, whose article is recommended. Also of interest here is the study by Blok and colleagues, who performed positron emission tomography (PET) studies in volunteer subjects during micturition. Increased blood flow was detected in the right pontine tegmentum, periaqueductal region, hypothalamus, and right inferior frontal cortex. When the bladder was full but subjects were prevented from voiding, increased activity was seen in the right ventral pontine tegmentum. The meaning of these lateralized findings is unclear, but the study supports the presumption that pontine centers are involved in the act of voiding.

The act of micturition is both reflex and voluntary. When the normal person desires to void, there is first a voluntary relaxation of the perineum, followed sequentially by an increased tension of the perineum, followed sequentially by an increased tension of the perineal muscles (DeGroat). It is useful to think of the detrusor contraction as a spinal stretch reflex, subject to facilitation and inhibition from higher centers. Voluntary closure of the external sphincter and contraction of the perineal muscles cause the detrusor contraction to subside. The abdominal muscles have no power to initiate micturition except when the detrusor muscle is not functioning normally. The voluntary restraint of micturition is a cerebral affair and is mediated by fibers that arise in the frontal lobes (paracentral motor region), descend in the spinal cord just anterior and medial to the corticospinal tracts, and terminate on the cells of the anterior horns and intermediolateral cell columns of the sacral segments, as described above. The co-
ordination of detrusor and external sphincteric function depends mainly on the descending pathway from the posited centers in the dorsolateral pontine tegmentum.

With regard to the neurologic diseases that cause bladder dysfunction, multiple sclerosis, usually with urinary urgency, is by far the most common. In Fowler’s clinic, other spinal cord disorders accounted for 12 percent of cases, degenerative diseases (Parkinson disease and multiple system atrophy) for 14 percent, and frontal lobe lesions for 9 percent.

These data and the physiologic principles elaborated above enable one to understand the effects of the following lesions on bladder function:

1. **Complete destruction of the cord below T12**, i.e., the conus, as from trauma, myelodysplasias, tumor, venous angioma, and necrotizing myelitis. The bladder is paralyzed for voluntary and reflex activity and there is no awareness of the state of fullness; voluntary initiation of micturition is impossible; the tonus of the detrusor muscle is abolished and the bladder distends as urine accumulates until there is overflow incontinence; voiding is possible only by the Crédé maneuver, i.e., lower abdominal compression and abdominal straining. Usually the anal sphincter and colon are similarly affected, and there is “saddle” anesthesia and abolition of the bulbocavernosus and anal reflexes as well as the tendon reflexes in the legs. The cystometrogram shows low pressure and no emptying contractions.

2. **Disease of the sacral motor neurons in the spinal gray matter, the anterior sacral roots, or peripheral nerves innervating the bladder**, as in lumbosacral meningomyelocele and the tethered cord syndrome. This is, in effect, a lower motor neuron paralysis of the bladder. The disturbance of bladder function is the same as in (1) above except that sacral and bladder sensation are intact. Various causes pertain in cauda equina disease, the most frequent being compression by epidural tumor or disc, neoplastic meningitis, and radiculitis from herpes or cytomegalovirus. It is noteworthy that a hysterical patient can suppress motor function and suffer a similar distention of the bladder (see below).

3. **Interruption of sensory afferent fibers** from the bladder, as in diabetes and tubas dorsalis, leaving motor nerve fibers unaffected. This is a primary sensory bladder paralysis. The disturbance in function is the same as in (1) and (2) above. Although a flaccid (atonic) paralysis of the bladder may be purely motor or sensory, as described above, in most clinical situations there is interruption of both afferent and efferent innervation, as in cauda equina compression or severe polyneuropathy. Neuropathies affecting mainly the small fibers are the ones usually implicated (diabetes, amyloid, etc.), but urinary retention also occurs in certain acute neuropathies such as Guillain-Barré syndrome.

4. **Upper spinal cord lesions, above T12**. These result in a reflex neurogenic (spastic) bladder. In addition to multiple sclerosis and traumatic myelopathy, which are the commonest causes, myelitis, spondylosis, arteriovenous malformation (AVM), syringomyelia, and tropical spastic paraparesis may cause a bladder disturbance of this type. If the cord lesion is of sudden onset, the detrusor muscle suffers the effects of spinal shock. At this stage, urine accumulates and distends the bladder to the point of overflow. As the effects of spinal shock subside, the detrusor usually becomes reflexly overactive, and since the patient is unable to inhibit the detrusor and control the external sphincter, urgency, precipitant micturition, and incontinence result. Incomplete lesions result in varying degrees of urgency in voiding. With slowly evolving processes involving the upper cord, such as multiple sclerosis, the bladder spasticity and urgency worsen with time and incontinence becomes more frequent. In addition, initiation of voluntary micturition is impaired and bladder capacity is reduced. Bladder sensation depends on the extent of involvement of sensory tracts. Bulbocavernosus and anal reflexes are preserved. The cystometrogram shows uninhibited contractions of the detrusor muscle in response to small volumes of fluid. Most puzzling to the authors have been cases of cervical cord injury in which reflex activity of the sacral mechanism does not return; the bladder remains hypotonic.

5. **Mixed type of neurogenic bladder**. In diseases such as multiple sclerosis, subacute combined degeneration, tethered cord, and syphilitic meningomyelitis, bladder function may be deranged from lesions at multiple levels, i.e., spinal roots, sacral nerves or their fibers of exit, and higher spinal segments. The resultant picture is a combination of sensory, motor, and spastic types of bladder paralysis.

6. **Stretch injury of the bladder wall**, as occurs with anatomic obstruction at the bladder neck and occasionally with voluntary retention of urine, as in hysteria. Repeated overdistention of the bladder wall often results in varying degrees of decompen-sation of the detrusor muscle and permanent atonia or hypotonia, although the evidence for this mechanism is uncertain. The bladder wall becomes fibrotic and bladder capacity is greatly increased. Emptying contractions are inadequate, and there is a large residual volume even after the Crédé maneuver and strong contraction of the abdominal muscles. As with motor and sensory paralyses, the patient is subject to cystitis, ureteral reflux, hydronephrosis and pyelonephritis, and calculus formation.

Urinary retention has been observed in women with polycystic ovaries. In one study of 62 such women, it was found that myotonic-like discharges activated the urethral sphincter, interfering with its relaxation during micturition. There were increasing amounts of residual urine, followed, finally, by complete retention. This obscure mechanism has been offered as an explanation of some cases of hysterical urinary retention. Fowler describes unusual patterns of electromyographic (EMG) activity in the bladder and sphincter of patients we would have classified as hysterical urine retention.

7. **Frontal lobe incontinence**. Often the patient, because of his abulic or confused mental state, ignores the desire to void and the subsequent incontinence. There is also a supranuclear type of hyperactivity of the detrusor and precipitant evacuation. These types of frontal lobe incontinence are considered on page 393.

8. **Nocturnal enuresis, or urinary incontinence during sleep**, due presumably to a delay in acquiring inhibition of micturition, is discussed in Chap. 19.

As discussed earlier, a role for pontine centers in human micturition is implied from animal experiments; to our knowledge, there are no well-studied examples of human bladder dysfunction due solely to a brainstem lesion. There are few clinical data except perhaps the PET studies mentioned to support the existence of these
centers, but Sakakibara and colleagues have reported that half of their patients with brainstem strokes had urinary symptoms, for which lesions in the pons were most often responsible; the precision of anatomic localization of the strokes was limited and the symptoms varied.

**Therapy of Disordered Micturition** Several drugs are useful in the management of flaccid and spastic disturbances of bladder function. In the case of a flaccid paralysis, betanechol (Urecholine) produces contraction of the detrusor by direct stimulation of its muscarinic cholinergic receptors. In spastic paralysis, the detrusor can be relaxed by propantheline (Pro-Banthine, 15 to 30 mg three times daily), which acts as a muscarinic antagonist, and by oxybutynin (Ditropan, 5 mg two to three times daily), which acts directly on the smooth muscle and also has a muscarinic antagonist action. Atropine, which is mainly a muscarinic antagonist, only partially inhibits detrusor contraction.

More recently, alpha1, sympathomimetic blocking drugs such as terazosin, doxazosin, and tamsulosin have been used to relax the urinary sphincter and facilitate voiding. Their widest use has been in men with prostatic hypertrophy, but they may be beneficial in patients with dysynergia of the sphincter from neurologic disease. Several other drugs may be useful in the treatment of neurogenic bladder but can be utilized rationally only on the basis of sophisticated urodynamic investigations (Krate and Siroky).

Often the patient must resort to intermittent self-catheterization, which can be safely carried out with scrupulous attention to sterile technique (washing hands, disposable catheter, etc.). Some forms of chronic antibiotic therapy and acidification of urine with vitamin C (1000 g/day) are practical aids, but their use has gone through cycles of popularity based on various studies with differing results. In selected paraplegic patients, the implantation of a sacral anterior root stimulator may prove to be helpful in emptying the bladder and achieving continence (Brindley et al).

**Disturbances of Bowel Function**

The colon and anal sphincters are obedient to the same principles that govern bladder function. Ileus from spinal shock, reflex neurogenic colon, and sensory and motor paralysis with megacolon are all recognized clinical entities. The colon, stomach, and small intestine may be hypotonic and distended and the anal sphincters lax, either from deafferentation, de-efferentation, or both. The anal and, in the male, the bulbocavernosus reflex may be abolished. Defecation may be urgent and precipitant with higher spinal and cerebral lesions. Since the same spinal segments and nearly the same spinal tracts subserve bladder and bowel function, meningo(myelo)celes and other cauda equina and spinal cord diseases often cause so-called double incontinence. However, since the bowel is less often filled and its content is usually solid, fecal incontinence is less frequent than urinary incontinence.

In recent years there has been considerable interest in weakness of the muscles of the pelvic floor as a cause of double incontinence, more so in the female. Also, it has been suggested that paradoxical contraction of the puborectus and external anal sphincter may be a cause of severe constipation (anismus). Extreme degrees of descent of the pelvic floor are believed to injure the pudendal nerves, as reflected in prolonged terminal latencies in nerve conduction studies.

Systemic diseases may affect the colonic sphincters; examples are myotonic dystrophy and scleroderma, which may weaken the internal sphincter, and polymyositis and myasthenia gravis, which may impair the function of the external sphincter (Schuster). The inability to control flatulence may be an early sign of sphincteric weakness in myasthenia. Also, sphincteric damage may complicate hemorrhoidectomy.

The serotonin receptor agonist cisapride had been used in partially restoring gastrointestinal motility in some cases of neurogenic ileus as, for example, the early stages of the Guillain-Barré syndrome and in pediatric bowel diseases. Because of arrhythmias and a few cases of sudden cardiac death, its administration is currently allowed only when given by experienced pediatric gastroenterologists.

Many cases of ileus, even to the extent of megacolon, have a pharmacologic basis, being due to the use of drugs that paralyze the parasympathetic system or narcotics that have a direct effect on the motility of gastrointestinal smooth muscle.

**Congenital Megacolon (Hirschsprung Disease)** This is a rare disease affecting mainly male infants and children. It is due to a congenital absence of ganglion cells in the myenteric plexus. The internal anal sphincter and rectosigmoid are involved most often and are the parts affected in restricted forms of Hirschsprung disease (75 percent of cases), but the aganglionosis is sometimes more extensive. The aganglionic segment of the bowel is constricted and cannot relax, thus preventing propagation of peristaltic waves, which, in turn, produces retention of feces and massive distention of the colon above the aganglionic segment. Enterocolitis is the most serious complication and is associated with a high mortality. Some cases of megacoloureter are attributed to a similar defect. Hirschsprung disease in most cases has been traced to a mutation of the RET oncogene; the variability in clinical severity corresponds to polymorphisms in the responsible gene. Other genes, such as the one that codes for the endothelin receptor, are implicated in a small group with the disease.

**Disturbances of Sexual Function**

Sexual function in the male, which is not infrequently affected in neurologic disease, may be divided into several parts: (1) sexual impulse, drive, or desire, often referred to as libido, discussed in Chap. 25; (2) penile erection, enabling the act of sexual intercourse (potency); and (3) ejaculation of semen by the prostate through the urethra.

The arousal of libido in men and women may result from a variety of stimuli, some purely imaginary. Such neocortical influences involve the limbic system and are transmitted to the hypothalamus and spinal centers. The suprasegmental pathways traverse the lateral funiculi of the spinal cord near the corticospinal tracts to reach sympathetic and parasympathetic segmental centers. Penile erection is effected through sacral parasympathetic motor neurons (S3 and S4), the nervi erigentes, and pudendal nerves. There is some evidence also that a sympathetic outflow from thoracolumbar segments (originating in T12–L1) via the inferior mesenteric and hypogastric plexuses can mediate psychogenic erections in patients with complete sacral cord destruction. Activation from these segmental centers opens vascular channels between arteriolar branches of the pudendal arteries and the vascular spaces of the corpora cavernosa and corpus spongiosum (erectile tissues), resulting in tumescence. Detumescence occurs when venous channels open widely. Ejaculation involves rhythmic contractions of the prostate, compressor (sphincter) urethrae, and bulbocavernosus and
ischiocavernosus muscles, which are under the control of both the sympathetic and parasympathetic centers. Afferent segmental influences arise in the glans penis and reach parasympathetic centers at S3 and S4 (reflexogenic erections). The organization of this neural system and the locations of lesions that can abolish normal potency are shown in Fig. 26-6. Similar neural arrangements exist in females.

The different aspects of sexual function may be affected separately. Loss of libido may depend on both psychic and somatic factors. It may be complete, as in old age or in medical and endocrine diseases, or it may occur only in certain circumstances or in relation to a certain situation or individual. In the latter case, which is due to psychologic factors, reflex penile erection during rapid-eye-movement (REM) sleep and even emission of semen may occur, and effective sexual intercourse in other circumstances is possible.

Sexual desire can on occasion be altered in the opposite direction, i.e., it may be excessive. This too may be psychologic or psychiatric in origin, as in manic states, but sometimes it occurs with neurologic disease, such as encephalitis and tumors that affect the diencephalon, septal region, and temporal lobes; with the dementias; and as a result of certain medications such as L-dopa, as discussed in Chap. 25. In the instances of neurologic diseases, there are usually other signs of disinhibited behavior as well.

On the other hand, sexual drive may be present but penile erection impossible to attain or sustain, a condition called impotence, in which nocturnal erections may or may not be preserved. The commonest cause of impotence is a depressive state. Prostatectomy is another, the result of damage to the parasympathetic nerves embedded in the capsule of the gland. It occurs also in patients who suffer disease of the sacral cord segments and their afferent and efferent connections (e.g., cord tumor, myelitis, tabs, and diabetic and many other polyneuropathies), in which case nocturnal erections are absent. The parasympathetic nerves cannot then be activated to cause tumescence of the corpora cavernosa and corpus spongiosum. The phosphodiesterase inhibitors such as sildenafil (Viagra) have proved to be useful in the treatment of impotence in some patients with sexual dysfunction of neurologic cause. During sexual stimulation, it enhances the effect of local nitrous oxide on the smooth muscle of the corpus cavernosum; this results in relaxation of the smooth muscle and inflow of blood. The high rate of success of this drug in patients with spinal cord injury indicates that segmental innervation is all that is required for reflexive erection in response to tactile stimulation of the penis.

Diseases of the spinal cord may abolish psychogenic erections, leaving reflexogenic ones intact. In fact, the latter may become overactive, giving rise to sustained painful erections (priapism). This indicates that the segmental mechanism for penile erection is relatively intact. There are many other nonneurologic causes for priapism, among them sickle cell anemia and other thrombotic states and perineal trauma.

Other sexual difficulties include the premature ejaculation of semen. After lumbar sympathectomy, the semen may be ejected back into the bladder because of paralysis of the perirethral muscle within the prostate, at the verumontanum (colliculus seminalis). Polyneuropathies such as those due to diabetes may be responsible; prostatism may have a similar effect.

There are also aberrations of sexual function that occur in the female, but they are more difficult to analyze. Lack of sexual desire or failure to attain orgasm (frigidity) is much more frequent in the female than in the male, occurring in a significant percentage of neurotic women and in others who exhibit no signs of psychic disorder. The activation of the pelvic reflexes involved in female orgasm is highly variable. The pelvic reflexes are sometimes congenitally deficient and the woman is anorgasmic but still sexually active and fertile. States of excessive sexual excitability are known in sociopathic individuals and, rarely, in those who suffer disease of the brain. Fecundity and sterility are usually unrelated to the other aspects of sexuality.

The genesis of sexual perversions is discussed in Chap. 56. Their origin remains obscure. Endocrine, biochemical, and psychologic studies have failed to clarify the cause and mechanism. Cerebral disorders of sexual function are discussed further in Chap. 25 (page 449) and the development of sexual function in Chap. 28.

**NERVOUS SYSTEM CONTROL OF RESPIRATION**

Considering the fact that the act of breathing is entirely neurologic, it is surprising how little attention it has received other than from
physiologists. Every component of breathing—the lifelong automatic cycling of inspiration, the transmission of coordinated nerve impulses to and from the respiratory muscles, the translation of systemic influences such as acidosis to the neuromuscular apparatus of the diaphragm—is under neural control. Moreover, respiratory failure is one of the most disastrous disturbances of neuromotor function in comatose states and in neuromuscular diseases such as myasthenia gravis, Guillain-Barré syndrome, amyotrophic lateral sclerosis, muscular dystrophy, and poliomyelitis. The major part of the treatment of these disorders consists of measures that assist respiration (mechanical ventilators). Finally, death—or brain death—is now virtually defined in terms of the ability of the nervous system to sustain respiration, a reversion to ancient methods of determining the cessation of all vital forces. A full understanding of respiration requires knowledge of the mechanical and physiologic workings of the lungs as organs of gas exchange; but here we limit our remarks to the nervous system control of breathing. Neurologists should be familiar with the alterations of respiration caused by diseases in different parts of the nervous system, the effects of respiratory failure on the brain, and the rationale that underlies modern methods of treatment.

The Central Respiratory Motor Mechanisms

It has been known for more than a century that breathing is controlled mainly by the lower brainstem, and that each half of the brainstem is capable of producing an independent respiratory rhythm. In patients with poliomyelitis, for example, the occurrence of respiratory failure was associated with lesions in the ventrolateral tegmentum of the medulla (Feldman, Cohen). Until recently, thinking on this subject was dominated by Lumsden’s scheme of the breathing patterns that resulted from sectioning the brainstem of cats at various levels. He postulated the existence of several centers in the pontine tegmentum, each corresponding to an abnormal breathing pattern—a pneumotaxic center, an apneustic center, and a medullary gasping center. This scheme proves to be oversimplified when viewed in the light of modern physiologic experiments. It appears that neurons in several discrete regions discharge with each breath and, together, generate the respiratory rhythm. In other words, these sites do not function in isolation, as individual oscillators, but interact with one another to generate the perpetual respiratory cycle and they each contain both inspiratory and expiratory components.

Three paired groups of respiratory nuclei are oriented more or less in columns in the pontine and medullary tegmentum (Fig. 26-7). They comprise (1) a ventral respiratory group (referred to as VRG), extending from the lower to the upper ventral medulla, in the region of the nucleus retroambiguus; (2) a dorsal medullary respiratory group (DRG), located dorsal to the obex and immediately ventromedial to the nucleus of the tractus solitarius (NTS); and (3) two clusters of cells in the dorsolateral pons in the region of the parabrachial nucleus. From electrical stimulation experiments, it appears that paired neurons in the dorsal pons may act as

Figure 26-7. The location of the main centers of respiratory control in the brainstem as currently envisioned from animal experiments and limited human pathology. There are three paired groups of nuclei: A. The dorsal respiratory group (DRG), containing mainly inspiratory neurons, located in the ventrolateral subnucleus of the nucleus of the tractus solitarius; B. A ventral respiratory group (VRG), situated near the nucleus ambiguus and containing in its caudal part neurons that fire predominantly during expiration and in its rostral part neurons that are synchronous with inspiration—the latter structure merges rostrally with the Botzinger complex, which is located just behind the facial nucleus and contains neurons that are active mostly during expiration; C. A pontine pair of nuclei (PRG), one of which fires in the transition between inspiration and expiration and the other between expiration and inspiration. The intrinsic rhythmicity of the entire system probably depends on interactions between all these regions, but the “pre-Botzinger” area in the rostral ventromedial medulla may play a special role in generating the respiratory rhythm. (Adapted by permission from Duffin et al.)
“on-off” switches in the transition between inspiration and expiration.

Inspiratory neurons are concentrated in the dorsal respiratory group and in the rostral portions of the ventral group, some of which have monosynaptic connections to the motor neurons of the phrenic nerves and the nerves to the intercostal muscles. Normal breathing is actively inspiratory and only passively expiratory; however, under some circumstances of increased respiratory drive, the internal intercostal muscles and abdominal muscles actively expel air. The expiratory neurons that mediate this activity are concentrated in the caudal portions of the ventral respiratory group and in the most rostral parts of the dorsal group. On the basis of both neuroanatomic tracer and physiologic studies, it has been determined that these expiratory neurons project to spinal motor neurons and have an inhibitory influence on inspiratory neurons.

The pathway of descending fibers that arises in the inspiratory neurons and terminates on phrenic nerve motor neurons lies just lateral to the anterior horns of the upper three cervical cord segments. When these tracts are damaged, automatic but not voluntary diaphragmatic movement on that side is lost. As noted below, the fibers carrying voluntary motor impulses to the diaphragm course more dorsally in the cord. The phrenic motor neurons form a thin column in the medial parts of the ventral horns, extending from the third through fifth cervical cord segments. Damage to these neurons, of course, precludes both voluntary and automatic breathing.

The exact locus from which the breathing rhythm is generated, if there is such a site, is not known. The conventional teaching has been that the dorsal respiratory group (DRG) was the dominant generator of the respiratory rhythm, but the situation is certainly more complex. Animal experiments have focused attention instead on the rostral ventrolateral medulla (VRG). This region contains a group of neurons in the vicinity of the “Botzinger complex” (which itself contains neurons that fire mainly during expiration). Cooling of this area or injection with neurotoxins causes the respiratory rhythm to cease (see the review by Duffin et al). It has been shown that the paired respiratory nuclei in the pons that are thought to act as switches between inspiration and expiration also possess a degree of autonomous rhythmicity, but their role in engendering cyclic breathing has not been clarified. Some workers are of the opinion that two or more sets of neurons in the VRG create a rhythm by their reciprocal activity or that oscillations arise within even larger networks (see Blessing for details). There are also centers in the pons that do not generate respiratory rhythms but may, under extreme circumstances, greatly influence them. One pontine group, the “pneumotaxic center,” modulates the response to hypoxia, hypocapnia, and lung inflation. In general, expiratory neurons are located laterally and inspiratory neurons medially in this center, but there is an additional group that lies between them and remains active during the transition between respiratory phases. Also found in the lower pons is a group of neurons that prevent unrestrained activity of the medullary inspiratory neurons (“apneustic center”). In addition to these ambiguities regarding a “center” for the generation of respiratory rhythm, there is the difficulty that the nuclei described above are not well defined in humans.

As to the effects of a unilateral brainstem lesion on ventilation, numerous cases of hypoventilation or total loss of automatic ventilation (“Ondine’s curse”—see further on) have been recorded (Bogousslavsky et al). We have observed several such remarkable cases as well, due in most instances to a large lateral medullary infarction. If the neural oscillators on each side were totally independent, such a syndrome should not be possible. The likely explanation may be that a unilateral lesion interrupts the connections between each of the paired groups of nuclei, which normally synchronize the two sides in the generation of rhythmic bursts of excitatory impulses to spinal motor neurons. It is of interest that in a case of a very delimited metastasis to the NTS there was no apparent impact on the breathing pattern until a terminal respiratory arrest (Rhodes and Wightman).

**Voluntary Control of Breathing** During speech, swallowing, breath-holding, or voluntary hyperventilation, the automaticity of the brainstem mechanisms of respiration is arrested in favor of reflexive or of conscious control of diaphragmatic contraction. The observations of Colebatch and coworkers, utilizing PET scanning, indicate that voluntary control of breathing is associated with activity in the motor and premotor cortex. The experiments of Maskill and associates demonstrated that magnetic cortical stimulation of a region near the cranial vertex activates the diaphragm. Although automatic and voluntary breathing utilize the same pools of cervical motor neurons that give rise to the phrenic nerves, the descending cortical pathways for voluntary breathing are distinct from those utilized by automatic brainstem mechanisms. It is not known whether the voluntary signal bypasses the brainstem mechanisms or is possibly integrated there. When both dorsal descending tracts subserving voluntary control are interrupted, as in the “locked-in syndrome,” the independent, automatic respiratory system in the medulla is capable of maintaining an almost perfectly regular breathing rate of 16 per minute with uniform tidal volumes.

These essential facts do not fully depict the rich interactions between the neuronal groups governing respiration and between the neurons for laryngeal and glottic activity that come into play during such coordinated acts as swallowing, sneezing, and coughing, and speaking. The brainstem regions involved in holding breathing in abeyance while swallowing occurs are pertinent to aspiration, a common feature of many neurologic diseases, as discussed further on. The drive applied to these systems is damped in processes such as Parkinson disease and may contribute to the problem of aspiration, as also discussed further on.

**Afferent Respiratory Influences** A number of signals that modulate respiratory drive originate in chemoreceptors located in the carotid artery. These receptors are influenced both by changes in pH and by hypoxia. Chemoreceptor afferents pass along the carotid sinus nerves, which join the glossopharyngeal nerves and terminate in the NTS. Aortic body receptors, which are less important as detectors of hypoxia, send afferent volleys to the medulla through the aortic nerves, which join the vagus nerves. There are also chemoreceptors in the brainstem, but their precise location is uncertain. Their main locus is thought to be in the ventral medulla, but other areas that are responsive to changes in pH have been demonstrated in animals. What is clear is that these regions are sensitive not to the pH of CSF, as had been thought, but to the hydrogen content of the extracellular fluid of the medulla.

Numerous stretch receptors within smooth muscle cells of the airways also project via the vagus nerves to the NTS and influence the depth and duration of breathing. Afferent signals from these specialized nerve endings mediate the Hering-Breuer reflex, described in 1868—a shortened inspiration and decreased tidal volume triggered by excessive lung expansion. The Hering-Breuer mechanism seems not to be important at rest, since bilateral vagal section has no effect on the rate or depth of respiration. These aspects of afferent pulmonary modulation of breathing have been...
reviewed by Berger and colleagues. It is interesting, however, that patients with high spinal transections and inability to breathe can still sense changes in lung volume, attesting to a nonspinal afferent route to the brainstem from lung receptors, probably through the vagus nerves. In addition, there are receptors located between pulmonary epithelial cells that respond to irritants such as histamine and smoke. They have been implicated in the genesis of asthma. Also there are “J-type” receptors that are activated by substances in the interstitial fluid of the lungs. These are capable of inducing hyperpnea and probably play a role in driving ventilation under conditions of pulmonary edema. Both the diaphragm and the accessory muscles of respiration contain conventional spindle receptors, but their role is not clear; all that can be said is that the diaphragm has a paucity of these receptors compared with other skeletal muscles (a property shared with extraocular muscles) and is therefore not subject to spasticity with corticospinal lesions or to the loss of tone in states such as REM sleep, in which gamma motor neuron activity is greatly diminished.

**Dyspnea** The common respiratory sensations of breathlessness, air hunger, chest tightness, or shortness of breath, all subsumed under the term *dyspnea*, have defined neurophysiologic interpretation. In animals, Chen and colleagues from Eldridge’s laboratory have demonstrated that neurons in the thalamus and central midbrain tegmentum fire in a graduated manner as respiratory drive is increased. These neurons are influenced greatly byafferent information from the chest wall, lung, and chemoreceptors and are postulated to be the thalamic representation of sensation from the thorax that is perceived at a cortical level as dyspnea. However, functional imaging studies indicate that various areas of the cerebral cortex are activated by dyspnea, mainly the insula and limbic regions.

**Aberrant Respiratory Patterns** Many of the most interesting respiratory patterns observed in neurologic disease are found in comatose patients, and several of these patterns have been assigned localizing value, some of uncertain validity: *central neurogenic hyperventilation, apneas*, and *ataxic breathing*. These are discussed in relation to the clinical signs of coma (Chap. 17) and sleep apnea (Chap. 19). Some of the most bizarre cadences of breathing—those in which unwanted breaths intrude on speech or those characterized by incoordination of laryngeal closure, diaphragmatic movement, or swallowing or by respiratory tics—have occurred in paraneoplastic brainstem encephalitis. Similar incoordinated patterns occur in certain extrapyramidal diseases. Patterns such as episodic tachypnea up to 100 breaths per minute and loss of voluntary control of breathing were, in the past, noteworthy features of postencephalitic parkinsonism. In *Leeuwenhoek disease*, named for the discoverer of the microscope who described and suffered from the disease, there is a continuous epigastric pulsation and dyspnea in association with rhythmic bursts of activity in the inspiratory muscles—a respiratory myoclonus akin to palatal myoclonus (Phillips and Eldridge). Two such cases in our clinical material followed influenza-like illnesses and resolved slowly over months.

*Cheyne-Stokes breathing*, the common and well-known waxing and waning type of cyclic ventilation reported by Cheyne in 1818 and later elaborated by Stokes, has for decades been ascribed to a prolongation of circulation time, as in congestive heart failure; but there are data that support a primary neural origin of the disorder, particularly the observation that it occurs most often in patients with deep hemispherical lesions of the cerebral hemispheres.

Another striking aberration of ventilation is a loss of automatic respiration during sleep, with preserved voluntary breathing (“*Ondine’s curse*”). The term stems from the German myth in which Ondine, a sea nymph, condemns her unfaithful lover to a loss of all movements and functions that do not require conscious will. Patients with this condition are compelled to remain awake lest they stop breathing, and they must have nighttime mechanical ventilation to survive. Presumably the underlying pathology is one that selectively interrupts the ventrolateral descending medullocervical pathways that subserve automatic breathing. The syndrome has been documented in cases of unilateral and bilateral brainstem infarctions, hemorrhage, encephalitis (neoplastic or infectious—for example, due to *Listeria*), in Leigh syndrome, and recovery from traumatic Duret hemorrhages. The issue of a loss of automatic ventilation as a result of a unilateral brainstem lesion has been addressed above. The converse of this state, in which there is complete loss of voluntary control of ventilation but preserved automatic monorhythmic breathing, has also been described (Munschauer et al). Incomplete variants of this latter phenomenon are regularly observed in cases of brainstem infarction or severe demyelinating disease and may be a component of the “locked-in state.”

The *congenital central hypoventilation syndrome* is thought to be an idiopathic version of the loss of automatic ventilation (see Shannon et al). This rare condition begins in infancy with apneas and sleep disturbances of varying severity or later in childhood with signs of chronic hypoxia leading to pulmonary hypertension. As mentioned on page 345, several subtle changes in the arcuate nucleus of the medulla and a depletion of neurons in regions of the respiratory centers have been found in this condition, but further study is necessary.

Neurologic lesions that cause *hyperventilation* are diverse and widely located throughout the brain, not just in the brainstem. In clinical practice, episodes of hyperventilation are most often seen in anxiety and panic states. The traditional view of “central neurogenic hyperventilation” as a manifestation of a pontine lesion has been brought into question by the observation that it may occur as a sign of cerebral lymphoma, in which postmortem examination has failed to show involvement of the brainstem regions controlling respiration (Plum).

*Hiccup (singultus)* is a poorly understood phenomenon. It does not seem to serve any useful physiologic purpose, existing only as a nuisance, and is typically not associated with any particular disease. It may occur as a component of the lateral medullary syndrome (page 678), with masses in the posterior fossa or medulla, and occasionally with generalized elevation of intracranial pressure, brainstem encephalitis, or with metabolic encephalopathies such as uremia. Rarely, singultation may be provoked by medication, one possible offender in our experience being dexamethasone. Since the triggers of hiccup often seem to arise in epigastric organs adjacent to the diaphragm, it is considered to be a gastrointestinal reflex, more than a respiratory one. A physiologic study by Newsom Davis has demonstrated that hiccup is the result of powerful contraction of the diaphragm and intercostal muscles, followed immediately by laryngeal closure. This results in little or no net movement of air. He concluded that the projections from the brainstem responsible for hiccup are independent of the pathways that mediate rhythmic breathing. Within a single burst or run of hiccups, the frequency remains relatively constant, but at any one
time it may range anywhere from 15 to 45 per minute. The con-
tractions are most liable to occur during inspiration and they are
inhibited by therapeutic elevation of arterial carbon dioxide (CO₂)
tension. We cannot vouch for the innumerable home-brewed meth-
ods that are said to suppress hiccups (breath-holding, induced
fright, anesthetization or stimulation of the external ear canal or
concha, etc.); but where the neurologist is asked to help in an in-
tractable case of unknown origin (usually male), baclofen is some-
times effective.

Disorders of Ventilation Due to
Neuromuscular Disease

Failure of ventilation in the neuromuscular diseases presents as
one of two symptom complexes: one occurs in patients with acute
generalized weakness, such as Guillain-Barré syndrome and my-
asthenia gravis, and the other in patients with subacute or chronic
diseases, such as motor neuron disease, certain myopathies (acid
maltase, nemaline), and muscular dystrophy. The review by
Polkey and colleagues provides a more extensive list. Patients in
whom respiratory failure evolves rapidly, in a matter of hours,
become anxious, tachycardic, and diaphoretic; they exhibit the
characteristic signs of diaphragmatic paralysis. They experience
paradoxical respiration, in which the abdominal wall retracts
during inspiration, owing to the failure of the diaphragm to con-
tract, while the intercostal and accessory muscles create a nega-
tive intrathoracic pressure. Or, there is respiratory alternans,
A pattern of diaphragmatic descent only on alternate breaths (this is
more characteristic of airway obstruction). These signs appear in
the acutely ill patient when the vital capacity has been reduced to
approximately 10 percent of normal, or approximately 500 mL in
the average adult. Patients with chronic but stable weakness of the respiratory
muscles, demonstrate signs of CO₂ retention, such as daytime som-
nolence, headache upon awakening, nightmares, and, in extreme
cases, papilledema. The accessory muscles of respiration are re-
cruited in an attempt to maximize tidal volume, and there is a ten-
dency for the patient to gulp or assume a rounded “fish mouth”
appearance in an effort to inhale additional air. In general, patients
with chronic respiratory difficulty tolerate lower tidal volumes
without dyspnea than do patients with acute disease, and symptoms
in the former may occur only at night, when respiratory drive is
diminished and compensatory mechanisms for obtaining additional
air are in abeyance.

Treatment of the two conditions differs. The chronic type of
respiratory failure may require only nighttime support of ventila-
tion, which can be provided by negative pressure devices such as
a cuirass or preferably, by intermittent positive pressure applied by
a tight-fitting mask over the nose (BIPAP or CPAP). These mea-
sures may also be used temporarily in acute situations, but in many
cases there will be need of a positive-pressure ventilator that pro-
vides a constant volume with each breath. This can be effected only
through an endotracheal tube. In patients with chronic weakness,
the use of a cough-assist machine to provide an artificial cough
three or four times a day is remarkably effective in preventing pulmonary infection.

Typical ventilator settings in cases of acute mechanical res-
piratory failure, if there is no pneumonia, are for tidal volumes of
8 to 10 mL/kg, depending on the compliance of the lungs and the
patient’s comfort, at a ventilator rate between 4 and 12 breaths per
minute, adjusted to the degree of respiratory failure. The tidal vol-
ume is kept relatively constant in order to prevent atelectasis, and
only the rate is changed as the diaphragm becomes weaker or
stronger. Decisions regarding the need for these mechanical devices
are frequently difficult, particularly since patients with chronic neu-omuscular illnesses often become dependent on a ventilator. Fur-
ther details regarding the management of ventilation in acute neu-omuscular weakness are given in the section on Guillain-Barré
syndrome on page 1126.

The presence of oropharyngeal weakness as a result of the
underlying neuromuscular disease may leave the patient’s airway
unprotected and require endotracheal intubation before mechanical
ventilation becomes necessary. It is also difficult to decide when
to remove the endotracheal tube in cases of oropharyngeal weak-
ness. Because the safety of the swallowing mechanism cannot be
assessed with the tube in place, one must be prepared to reintubate
the patient or to have a surgeon prepared to perform a tracheostomy
after extubation, in the event that aspiration occurs.

Not infrequently we encounter a patient in whom the earliest
feature of neuromuscular disease is subacute respiratory failure;
this is manifest as dyspnea and exercise intolerance but without
other overt signs of neuromuscular disease. Most such cases turn
out to have motor neuron disease, but rare instances of myasthenia
gravis, acid maltase deficiency, polymyositis, nemaline myopathy,
Lambert-Eaton syndrome, or chronic inflammatory demyelinating
polyneuropathy may present in this way. The neurologist may be
consulted in these cases after other physicians have found no evi-
dence of intrinsic pulmonary disease. The spirometric flow-volume
loop examination in mechanical-neuromuscular forms of respira-
tory failure shows low airflow rates with diminished lung volumes
that together simulate a restrictive lung disease. Among such pa-
patients we have also found instances of an apparently isolated uni-
lateral or bilateral phrenic nerve paresis, which had followed sur-
dery or an infectious illness. The problem is probably akin to
brachial neuritis (Parsonage-Turner syndrome, page 1165), in
which the phrenic nerve can be implicated.

Neuromuscular Respiratory Failure in Critically Ill Patients

Neurologists increasingly are being called upon to address the
question of an underlying neuromuscular cause for respiratory fail-
ure in a critically ill patient. Aside from the acute neuromuscular
diseases listed above, Bolton and colleagues have delineated a criti-
cal illness polyneuropathy, which accounts for the majority of in-
stances in which there is an inability to wean the patient from a
ventilator once the more conventional causes of pulmonary insuf-
siciency such as malnutrition and hypokalemia have been ad-
dressed. Such a critical illness polyneuropathy has been identified
by electromyography (EMG) in as many as 40 percent of patients
in medical intensive care units. Most of the patients have had an
episode of sepsis or have had multiple-organ failure (see Chap. 46).
Less often, a critical illness myopathy occurring in relation to ad-
imistration of high-dose corticosteroids (Chap. 51) has been the
cause of generalized weakness and respiratory failure. This unique
polymyopathy occurs mainly in patients who are receiving neuro-
muscular postsynaptic blocking drugs such as pancuronium with
the high-dose steroids (page 1237). Severe hypophosphatemia is
another cause of acute generalized weakness.

The Neurologic Basis of Swallowing

The act of swallowing, like breathing, continues periodically
through waking and sleep, largely without conscious will or aware-
ness. Swallowing occurs at a natural frequency of about once per
minute while an individual is idle; it is suppressed during concentration and emotional excitement.

The fundamental role of swallowing is to move food from the mouth to the esophagus and thereby to begin the process of digestion, but it also serves to empty the oral cavity of saliva and prevent its entry into the respiratory tract. Since the oropharynx is a shared conduit for breathing and swallowing, obligatory reflexes exist to assure that breathing is held in abeyance during swallowing. Because of this relationship and the frequency with which dysphagia and aspiration complicate neurologic disease, the neural mechanisms that underlie swallowing are of considerable importance to the neurologist and are described here. The reader is also referred to other parts of this book for a discussion of derangements of swallowing consequent upon diseases of the lower cranial nerves (Chap. 47), of muscle (Chap. 48), and of the neuromuscular junction (Chap. 53).

Anatomic and Physiologic Considerations A highly coordinated sequence of muscle contractions is required to move a bolus of food smoothly and safely through the oropharynx. This programmed activity may be elicited voluntarily or by reflex movements that are triggered by sensory impulses from the posterior pharynx. Swallowing normally begins as the tongue, innervated by cranial nerve XII, sweeps food to the posterior oral cavity, and brings the bolus into contact with the posterior wall of the oropharynx. As the food passes the pillars of the fauces, tactile sensation, carried through nerves IX and X, reflexly triggers (1) the contraction of levator and tensor veli palatini muscles, which close the nasopharynx and prevent nasal regurgitation, followed by (2) the upward and forward movement of the arytenoid cartilages toward the epiglottis (observed as an upward displacement of the hyoid and thyroid cartilages), which closes the airway. With these movements the epiglottis guides the food into the valleculae and into channels formed by the epiglottic folds and the pharyngeal walls. The airway is closed by sequential contractions of the arytenoid-epiglottic folds, and below them, the false cords, and then the true vocal cords, which seal the trachea. All of these muscular contractions are effected largely by cranial nerve X (vagus). The palatopharyngeal muscles pull the pharynx up over the bolus and the stylopharyngeal muscles draw the sides of the pharynx outward (nerve IX). At the same time, the upward movement of the larynx opens the cricopharyngeal sphincter. A wave of peristalsis then begins in the pharynx, pushing the bolus through the sphincter into the esophagus. These muscles relax as soon as the bolus reaches the esophagus. The entire swallowing ensemble can be elicited by stimulation of the superior laryngeal nerve (this route is used in experimental studies.)

Reflex swallowing requires only medullary functioning and is known to occur in the vegetative and locked-in states as well as in normal and anencephalic neonates. The integrated sequence of muscle activity for swallowing is organized in a region of brainstem that roughly comprises a swallowing center, located in the region of the NTS, close to the respiratory centers. This juxtaposition ostensibly allows the refined coordination of swallowing with the cycle of breathing. Besides a programmed period of apnea, there is a slight forced exhalation after each swallow that further prevents aspiration. The studies of Jean, Kessler and others (cited by Blessing), using microinjections of excitatory neurotransmitters, have localized the swallowing center in animals more precisely to a region adjacent to the termination of the superior laryngeal nerve.

Dysphagia and Aspiration Weakness or incoordination of the swallowing apparatus is manifest as dysphagia and, at times, aspiration. The patient himself is often able to discriminate one of several types of defect: (1) difficulty initiating swallowing, which leaves solids stuck in the oropharynx; (2) nasal regurgitation of liquids; (3) frequent coughing and choking immediately after swallowing and a hoarse, “wet cough” following the ingestion of fluids; or (4) some combination of these. Extrapyramidal diseases, notably Parkinson disease, reduce the frequency of swallowing and cause an incoordination of breathing and swallowing, as noted below.

It is surprising how often the tongue and the muscles that cause palatal elevation appear on direct examination to act normally despite an obvious failure of coordinated swallowing. In this regard, the use of the gag reflex as a neurologic sign is quite limited, being most helpful when there is a medullary lesion or the lower cranial nerves are affected. In our experience, palatal elevation in response to touching the posterior pharynx only demonstrates that cranial nerves IX and X and the local musculature are not entirely dysfunctional; however, the presence of the reflex does not assure the smooth coordination of the swallowing mechanism and, more importantly, does not obviate the risk of aspiration. It should also be emphasized that difficulties with swallowing may begin subtly and express themselves as weight loss or as a noticeable increase in the time required to swallow and to eat a meal. Nodding or sideways head movements to assist the propulsion of the bolus, or the need to repeatedly wash food down with water, are other clues to the presence of dysphagia. Sometimes recurrent minor pneumonias are the only manifestation of intermittent (“silent”) aspiration.

A defect in the initiation of swallowing is usually attributable to weakness of the tongue and may be a manifestation of myasthenia gravis, motor neuron disease, or, rarely, inflammatory disease of the muscle; it may be due to palsies of the 12th cranial nerve (metastases at the base of the skull or meningoradiculitis, carotid dissection), and to a number of other causes. In all these cases there is usually an associated dysarthria with difficulty pronouncing lingual sounds. The second type of dysphagia, associated with nasal regurgitation of liquids, indicates a failure of velopalatine closure and is characteristic of myasthenia gravis, 10th nerve palsy of any cause, or incoordination of swallowing due to bulbar or pseudobulbar palsy. A nasal pattern of speech with air escaping from the nose is a usual accompaniment.

Viewed from a physiologic perspective, the causes of aspiration fall into four main categories: (1) weakness of the pharyngeal musculature due to lesions of the vagus on one or both sides; (2) a myopathy (myotonic and oculopharyngeal dystrophies) or neuromuscular disease (amyotrophic lateral sclerosis and myasthenia gravis); (3) a medullary lesion that affects the NTS or the cranial motor nuclei (lateral medullary infarction is the prototype)—but
syringomyelia-syringobulbia and rarely multiple sclerosis, polio, and brainstem tumors may have the same effects; or (4) a less well defined mechanism of slowed or disordered swallowing arising from corticospinal disease (pseudobulbar palsy, hemispherical stroke) or from diseases of the basal ganglia (mainly Parkinson disease) that alter the timing of breathing and swallowing and permit the airway to remain open as food passes through the posterior pharynx. In the latter cases a decreased frequency of swallowing also causes saliva to pool in the mouth (leading to drooling) and adds to the risk of aspiration.

Although the case has been made above that swallowing is a brainstem reflex, aspiration and swallowing difficulty after severe stroke occur in a surprisingly large number of cases of cerebral infarction and hemiparesis without brainstem damage. The problem is most evident during the first few days after a hemispheric stroke on either side of the brain (Meadows). These effects last for weeks and render the patient subject to pneumonia and fever. In the clinical and fluoroscopic study by Mann and colleagues, half of patients still had manifest abnormalities of swallowing 6 months after their strokes. Some insight into the nature of swallowing dysfunction after stroke is provided by Hamdy and colleagues, who correlated the presence of dysphagia with a lesser degree of motor representation of pharyngeal muscles in the unaffected hemisphere, as assessed by magnetic stimulation of the cortex.

Pain on swallowing occurs under a different set of circumstances, the one of most neurologic interest being glossopharyngeal neuralgia (pages 163 and 1185).

Videofluoroscopy has become a useful tool in determining the presence of aspiration during swallowing and in differentiating the several types of dysphagia. The movement of the bolus by the tongue, the timing of reflex swallowing, and the closure of the pharyngeal and palatal openings are judged directly by observation of a bolus of food mixed with barium or of liquid barium alone. However, authorities in the field, such as Wiles, whose reviews are recommended (see also Hughes and Wiles), warn that unqualified dependence on videofluoroscopy is unwise. They remark that observation of the patient swallowing water and repeated observation of the patient while eating can be equally informative. Having the patient swallow water is a particularly effective test of laryngeal closure; the presence of coughing, wet hoarseness or breathlessness, and/or the need to swallow small volumes slowly are indicative of a high risk of aspiration.

Based on bedside observations and on videofluoroscopy studies, an experienced therapist can make recommendations regarding the safety of oral feeding, changes in the consistency and texture of the diet, postural adjustments, and the need to insert a tracheostomy or feeding tube.

REFERENCES

The hypothalamus plays three roles in the actions of the nervous system. The first, as the “head ganglion” of the autonomic nervous system, was described in the preceding chapter; the second, as the circadian and seasonal clock for behavioral and sleep-wake functions, was considered in Chap. 19, on sleep; and the third, as the neural center of the endocrine system, is the subject of this chapter. In the hypothalamus, these systems are integrated with one another as well as with neocortical, limbic, and spinal influences. Together, they maintain homeostasis and participate in the substructure of emotion and affective behavior.

The expansion of knowledge of neuroendocrinology during the past few decades stands as one of the significant achievements in neurobiology. It has been learned that neurons, in addition to transmitting electrical impulses, can synthesize and discharge complex molecules locally and into the systemic circulation, and that these molecules are capable of activating or inhibiting endocrine, renal, and vascular cells at distant sites.

The concept of neurosecretion probably had its origins in the observations of Speidel, in 1919 (and later those of the Scharrers in 1929), who noted that some of the hypothalamic neurons had the morphologic characteristics of glandular cells. Their suggestion that such cells might secrete hormones into the bloodstream was so novel, however, that it was rejected by most biologists at the time. This seems surprising now that neurosecretion is viewed as a fundamental part of the science of endocrinology.

Following these early observations, it was found that certain peptides secreted by neurons in the central and peripheral nervous systems were also contained in glandular cells of the pancreas, intestines, and heart. This seminal observation was made in 1931 by Euler and Gaddum, who isolated a substance from the intestines that was capable of acting on smooth muscle. But it was not until some 35 years later that Leeman and her associates purified the substance and identified it as substance P (see Aronin et al). Then followed the discovery of somatostatin by Brazeau and colleagues in 1973 and the endogenous opioids (enkephalin) by Hughes and coworkers in 1975; since then a series of hypothalamic releasing factors that act on the pituitary gland have been isolated.

THE HYPOTHALAMUS

Anatomic Features

The hypothalamus lies on each side of the third ventricle and is continuous across its floor. It is bounded posteriorly by the mammillary bodies, anteriorly by the optic chiasm and lamina terminalis, superiorly by the hypothalamic sulci, laterally by the optic tracts, and inferiorly by the hypophysis. It comprises three main nuclear groups, the standard nomenclature for which was proposed in 1939 by Rioch and colleagues: (1) the anterior group, which includes the preoptic, supraoptic, and paraventricular nuclei; (2) the middle group, which includes the tuberal, arcuate, ventromedial, and dorsomedial nuclei; and (3) the posterior group, comprising the mammillary and posterior hypothalamic nuclei.

Nauta and Haymaker have subdivided the hypothalamus sagittally. The lateral part lies lateral to the fornix; it is sparsely cellular and its cell groups are traversed by the medial forebrain bundle—which carries finely myelinated and unmyelinated ascending and descending fibers to and from the rostrally placed septal nuclei, substantia innominata, nucleus accumbens, amygdala, and piriform cortex—and the caudally placed segmental reticular formation. The medial hypothalamus is rich in cells, some of which are the neurosecretory cells for pituitary regulation and visceral control. It contains two main efferent fiber systems—the mammillothalamic tract of Vicq d’Azyr (named for the physician to Louis XIV, a paramour of Marie Antionette), which connects the mammillary nuclei with the anterior thalamic nucleus (which, in turn, projects to the cingulate gyrus), and the mammillolateral tract. Additional structures of importance are the stria terminalis, which runs from the amygdala to the ventromedial hypothalamic nucleus, and the fornix, which connects the hippocampus to the mammillary body, septal nuclei, and periventricular parts of the hypothalamus. The lateral and medial parts of the hypothalamus are interconnected and their functions are integrated.

The inferior surface of the hypothalamus, just posterior to the pituitary stalk, bulges downward slightly; this region is known as the tuber cinereum. From the center of the tuber arises the median eminence or infundibulum; the latter stands out because of its vascularity (the hypophysial-portal system of veins courses over the surface). The infundibulum extends into the pituitary stalk, which, in turn, enters the pars nervosa of the hypophysis (Fig. 27-1). The median eminence assumes special importance because of the intimate relation of its cell groups to the anterior lobe of the pituitary gland. It represents the interface between converging pathways from the brain and the master gland of the endocrine system. The supraopticotuberal fibers terminate on capillaries of the outer zone of the median eminence (Martin and Reichlin). The tuberoinfundibular neurons of the arcuate nucleus and anterior periventricular nuclei synthesize most of the releasing factors described below (Fig. 27-1).

The abundant blood supply of the hypothalamus (from several feeding arteries) is of importance to neurosurgeons who attempt to obliterate aneurysms that derive from adjacent vessels. Many small radicles, arising from the posterior and anterior communicating arteries as well as from the most proximal portions of the anterior and posterior cerebral arteries, form a network of such redundancy that infarction of the hypothalamus is infrequent.

Readers requiring a more extensive source of information on anatomic and other aspects of the hypothalamus are directed to the comprehensive material by Swaab in the two-volume Handbook of Clinical Neurology and to the monograph by Martin and Reichlin.
Growth Hormone–Releasing Hormone (GHRH)

This hormone and somatostatin (also known as GH-release inhibiting hormone, or SRH) are both secreted by specialized tuberoinfundibular neurons and released into the hypophyseal-portal circulation, by which they are carried to specific GH-secreting cells of the anterior pituitary gland (somatotropes). Immunohistochemical staining has shown the sources of GHRH and somatostatin to be neurons of the posterior part of the arcuate and ventromedial hypothalamic nuclei and other neurons of the median eminence and premammillary area. Somatostatin, a 14–amino acid peptide, is produced more anteriorly by neurons in the periventricular area and small-cell part of the paraventricular nucleus. The amygdala, hippocampus, and other limbic structures project to the arcuate nuclei via the medial corticohypothalamic tract (in the stria terminalis) and are believed to account for the sleep- and stress-induced fluctuations of GH and somatostatin. Also, it has been demonstrated that all four biogenic amines (dopamine, norepinephrine, epinephrine, and serotonin) influence GH regulation, as does acetylcholine, either by direct action on pituitary somatotropic cells or on hypothalamic regulatory neurons. TRH also increases GH from somatotropes. Many of the latter pituitary cells contain large cosinophilic granules, but others, previously identified incorrectly as chromophobe cells, also contain GH. Somatotropin C, a basic peptide that is synthesized in the liver, exerts feedback control of GH by inhibiting the pituitary somatotropes and stimulating the release of somatostatin. Growth hormone enhances skeletal growth by stimulating the proliferation of cartilage and growth of muscle. It also regulates lipolysis, stimulates the uptake of amino acids in cells, and has anti-insulin effects. The blood concentrations of GH fluctuate from 1 or 2 to over 60 ng/mL, being highest within the first hour or two after the onset of sleep.

Corticotropin-Releasing Hormone (CRH)

This hormone, a 41–amino acid peptide, acts synergistically with vasopressin to release adrenocorticotropic hormone (ACTH) from basophilic cells in the pituitary. ACTH stimulates the synthesis and release of the hormones of the adrenal cortex, mainly glucocorticoids (cortisol or hydrocortisone) but also mineralocorticoids (aldosterone) and androgens (converted in the tissues to testosterone). The neurons of origin of CRH lie in a particular part of the paraventricular nucleus, other cells of which form the paraventricular-supraopticocorticotroph hypophyseal tract (neurohypophysis) and elaborate vasopressin and oxytocin and several other substances (neurotensin, dynorphin, vasoactive intestinal peptide). These hypothalamic cells receive an extensive input from other regions of the nervous system, particularly via the noradrenergic pathways (from reticular neurons in the medulla and those of the locus ceruleus and tractus solitarius) and from many of the limbic structures. Presumably, these extra-hypothalamic connections provide the mechanism by which stress and pain activate the secretion of ACTH and cortisol. CRH itself is widely distributed in the brain. There is feedback control of CRH and ACTH via glucocorticoid receptors in the hypothalamus and anterior lobe of the pituitary. Serotonin and acetylcholine enhance ACTH secretion, whereas the catecholamines are inhibitory.

Gonadotropin-Releasing Hormone (GnRH)

This 10–amino acid peptide originates in the arcuate nucleus and is present in highest concentration near the median eminence. It effects the release of the two gonadotropins—luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The ovary and testis, by secreting a peptide called inhibin, are able to suppress FSH, as do gonadal steroids—i.e., estrogens. GnRH is under the influence of other neuronal systems, which are modulated by catecholamines, serotonin, acetylcholine, and dopamine. Puberty, menstruation, ovulation, laceration, and menopause are all related to the effects of GnRH, FSH, and LH on the ovaries, uterus, breasts, and testes. Normal levels of blood FSH are 2.5 to 4.9 ng/mL in prepuberty and 7.5 to 11 ng/mL in the adult; levels of blood LH are 2.8 to 9.6 ng/mL in prepuberty and 10 to 18 ng/mL in the adult.

Prolactin-Releasing Hormone (PRH)

This hormone is released by neurons in the region of the arcuate nucleus and activates lactotrophic cells of the anterior pituitary. However, a number of other
peptides—thyroid-releasing factor, vasoactive intestinal peptide, peptide-histidine-isoleucine, and oxytocin—also have the capacity to raise the levels of prolactin in the blood. The hypothalamic-pituitary axis is responsive to sensory stimuli from the nipples, via pathways in the spinal cord and brainstem, accounting for the effect of suckling on milk production. The normal blood levels of prolactin are 5 to 25 ng/mL. The release of prolactin is also influenced by an inhibitory dopaminergic innervation of pituitary lactotrophic cells. This latter mechanism accounts for galactorrhea and reproductive disorders, which occur with tumors that compress the pituitary stalk and interrupt the venous portal transport of dopamine from the hypothalamus.

The Neurohypophysis: Vasopressin and Oxytocin

The oligopeptides vasopressin and oxytocin are elaborated by cells of the supraoptic and paraventricular nuclei and are transported, via their axons, through the stalk of the pituitary to its posterior lobe, where these substances are stored. Together, these elements constitute the neurohypophysis (posterior pituitary), which develops as an evagination of the floor of the third ventricle. Some of the vasopressin-containing nerve endings also terminate on cells of origin of the autonomic nervous system and on the capillary plexus of the hypophysial portal circulation, through which they influence the secretion of CRH and GH. The peptide parts of vasopressin and oxytocin, whose chemical nature was determined by duVigneaud, are almost identical, differing from one another by only two amino acids.

Vasopressin, acting on the kidney tubules, serves as the antidiuretic hormone (ADH) and, complemented by thirst mechanisms, maintains the osmolality of the blood. Plasma osmolality modifies vasopressin secretion by acting directly on the supraoptic and paraventricular neurons or on separate osmoreceptors in the hypothalamus. The sensitivity of the vasopressin-ADH mechanism is demonstrated by the absence of antidiuretic effect when vasopressin is below 1 pg/mL and by maximal antidiuresis when plasma levels reach 5 pg/mL. If serum osmolality falls below 280 mosm/L, the release of ADH is completely inhibited. This system is most effective in maintaining homeostasis when serum osmolality is relatively close to the normal range, between 280 and 295 mosm/L.

Alterations in blood volume and pressure also affect vasopressin release through neural mechanisms that have their origin in baro- and mechanoreceptors of the aortic arch, carotid sinus, and right atrium. Afferent signals from these regions are conveyed in the vagus and glossopharyngeal nerves, which synapse in the nucleus of the tractus solitarius; the precise pathways to the hypothalamus have not been delineated, however. With severe hypotension, ADH release will continue even if there is a low serum osmolality, i.e., pressure predominates over osmolality as a stimulus. Vasopressin secretion is also influenced by nonosmotic factors. Nausea, for example, is a potent stimulus, raising levels of the hormone 100-fold. Hypoglycemia has a less profound effect. Drugs such as morphine, nicotine, alcohol, and certain chemotherapeutic agents (cyclophosphamide) also cause release of the stored peptide.

Pain, emotional stress, and exercise have long been thought to influence the hypothalamus. Thesensitivity of the vasopressin-ADH mechanism is demonstrated by the absence of antidiuretic effect when vasopressin is below 1 pg/mL and by maximal antidiuresis when plasma levels reach 5 pg/mL. If serum osmolality falls below 280 mosm/L, the release of ADH is completely inhibited. This system is most effective in maintaining homeostasis when serum osmolality is relatively close to the normal range, between 280 and 295 mosm/L.

Role of the Hypothalamus in Sexual Development (See also Chap. 28)

The hypothalamus also plays a critical role in the development of human sexuality and its expression, a theme elaborated in the next chapter. The suprachiasmatic nucleus and the number of neurons it contains is considerably larger in men than in women, a dimorphism that becomes evident during postnatal development. The interstitial nucleus of the hypothalamus is reportedly smaller in the homosexual male, evidence perhaps that homosexuality is a recognizable morphologic basis (Levy). This biological evidence has been sharply challenged (Byne). These issues are addressed further on page 503. The intimate relationship of the hypothalamus with the development of sexual characteristics at all stages of life is shown by the appearance, in the infundibular area, of hypertrophic neurons that are rich in estrogen receptors; it has been proposed that some of the symptoms of menarche are timed and mediated by these hypothalamic neurons. With aging, and more so in Alzheimer disease, the neuronal population in this region decreases markedly; the sleep disturbances of senescence and some aspects of the “sundowning” syndrome have also been attributed to this cell loss.

Regulation of Sympathetic and Parasympathetic Activity

Finally, the central role of the hypothalamus in the regulation of both sympathetic and parasympathetic activities must be emphasized. This aspect of hypothalamic function is discussed in the preceding chapter (pages 456 and 466).

The Pineal Gland and Melatonin

The pineal gland, or pineal body, is a small glandular structure (about 9 mm in diameter) that projects from the dorsal dienceph-
aloe and lies just posterior to the third ventricle. In the past the pineal body figured prominently in philosophic and religious writings; for Descartes it was the seat of the soul. When this idea was discredited, the pineal gland was relegated to the status of a vestigial organ. The identification of melatonin, the pineal hormone—followed by recognition of its role in maintaining biologic rhythms and the modulating effects on its secretion by the circadian light-dark cycle—revived scientific interest in the structure. Even though the hormone was found to have an indirect effect on several other neuroendocrine systems, neurologists took little interest in pineal function because ablation of the gland in humans, with attendant loss of most of the circulating melatonin, leads to few if any clinical changes.

It is the cyclic secretion of melatonin that appears to be the most important activity of the pineal gland. However, melatonin secretion is more accurately regarded as a linked manifestation of the circadian rhythm than as its controlling mechanism. The main cellular element of the gland, the pinealocyte, is thought to be derived from neural photoreceptors in lower vertebrates. The latter cells, structurally analogous to retinal cones, transduce light directly into neural impulses and are among the mechanisms for circadian entrainment of hormonal rhythms. In humans, the pineal no longer possesses the ability to transduce light directly. However, it does retain an input from photic stimuli and influences the circadian light-dark cycle through a pathway that originates in the retina, synapses in the suprachiasmatic nucleus, passes through descending sympathetic tracts to the intermediolateral cell columns and superior cervical ganglia, and then ascends to innervate noradrenergic terminals on the pinealocytes. Darkness elicits a release of norepinephrine from the photoreceptors, stimulating the synthesis and release of melatonin. During daylight the retinal photoreceptor cells are hyperpolarized, norepinephrine release is inhibited, and there is little melatonin production. The concentration of the hormone peaks between 2 and 4 A.M. and gradually falls thereafter. An approximate circadian rhythmicity to melatonin release is preserved in continuous darkness, and inexplicably, the blind maintain a light suppression of secretion. It is readily appreciated that, in humans, it is difficult to separate the changes that occur in the suprachiasmatic nucleus from those of the pineal.

Like other neuroendocrine cells, pinealocytes release peptides that are produced in the Golgi apparatus and packaged in secretory granules. Whether secretion is the main mechanism for melatonin release is unclear, because these cells can utilize an alternative ependymal type of vacuolar secretion. The entire gland is invested by a rich vasculature to receive the released peptide (in some mammals the blood flow per gram of pineal tissue is surpassed only by that of the kidney). The biochemistry and physiology of melatonin have been extensively reviewed by Brzozinski.

In humans, a regular feature of pineal pathology is the accumulation of calcareous deposits, commonly thought to be calcium but actually composed of carbonate-containing hydroxyapatite. These concretions are formed within vacuoles of pinealocytes and released into the extracellular space. This mineralization of the pineal body provides a convenient marker for its position in plain films and on various imaging studies.

It is of significance that pineal tumors do not secrete melatonin, but the loss of melatonin may be used as a marker for the completeness of surgical pinealectomy. Most interest in the past several years has centered around melatonin as a soporific agent and its potential to reset sleep rhythms. Its concentration in depressive illnesses, especially in the affected elderly, is also decreased.

### HYPOTHALAMIC SYNDROMES

Hypothalamic syndromes are of two distinct types (Martin and Reichlin). In one, all or many hypothalamic functions are disordered, often in combination with signs of disease in contiguous structures ("global hypothalamic syndromes," as described below). The second type is characterized by a selective loss of hypothalamic-hypophysial function, attributable to a discrete lesion of the hypothalamus and often resulting in a deficiency or overproduction of a single hormone—a partial hypothalamic syndrome.

#### Global Hypothalamic Syndromes

A variety of lesions can invade and destroy all or a large part of the hypothalamus. These include sarcoid and other granulomatous diseases, an idiopathic inflammatory disease, and germ-cell and other tumors.

The hypothalamus is involved in approximately 5 percent of cases of sarcoidosis, sometimes as the primary manifestation of the disease, but more often in combination with facial palsy and hilar lymphadenopathy. An elevation of angiotensin-converting factor, particularly in the cerebrospinal fluid (CSF), confirms the diagnosis. The lesions are visible by magnetic resonance imaging (MRI) (see Fig. 32-2).

Tumors that involve the hypothalamopituitary axis include metastatic carcinoma, lymphoma, craniopharyngioma, and a variety of germ-cell tumors. The latter (reviewed by Jennings et al) include germinomas, teratomas, embryonal carcinoma, and chorionic carcinoma. They develop during childhood, tend to invade the posterior hypothalamus, and are accompanied in some instances by an increase in serum alpha fetoprotein or the beta subunit of chorionic gonadotropin. A unique syndrome of gelastic epilepsy is caused by a hamartoma of the hypothalamus (see Chap. 16).

Among the inflammatory conditions, infundibuloneurohypophysitis, or infundibulitis, is a cryptogenic inflammation of the neurohypophysis and pituitary stalk, with thickening of these parts by infiltrates of lymphocytes (mainly T cells) and plasma cells (Imura et al). It is thought to be an autoimmune disorder. Histiocytosis X—a group of diseases comprising Letterer-Siwe disease, Hand-Schüller-Christian disease, and eosinophilic granuloma—implies multiple organs, including the hypothalamus and neighboring structures and leptomeninges (often causing cells to appear in the CSF). These conditions of children pursue an indolent course. The cell type is a proliferating histiocyte.

#### Partial Hypothalamic Syndromes

**Diabetes Insipidus (DI)*** This is a state of polyuria with dilute urine and polydypsia that results in the loss of action of antidiuretic hormone. As long ago as 1913, Farini of Venice and von den Velden of Dusseldorf (quoted by Martin and Reichlin) independently discovered that DI was associated with destructive lesions of the hypothalamus. They showed, moreover, that in patients with this disorder, the polyuria could be corrected by injections of extracts of the posterior pituitary. Ranson elucidated the anatomy of the neurohypophysis; the Scharrers traced the posterior pituitary secretion to granules in the cells of the supraoptic and paraventricular nuclei and followed their passage to axon terminals in the posterior lobe of the pituitary. DuVigneaud and colleagues determined the chemical structure of the two neurohypophysial peptides, vasopressin and oxytocin, of which these granules were composed.
These observations opened up the entire field of neuroendocrinology.

As already stated, the usual cause of DI is a lack of vasopressin (antidiuretic hormone, or ADH) as a result of a lesion of the neurohypophysis. This leads to a reduction in its action in the kidneys, where it normally promotes the absorption of water. As a consequence there is diuresis of low-osmolar urine (polyuria), reduction in blood volume, and increased thirst and drinking of water (polydipsia) in an attempt to maintain osmolality. A congenital abnormality of renal tubular epithelium or destruction of the epithelium has a similar effect—nephrogenic DI. DI is also of interest to the neurologist because of its association with lithium toxicity, which impairs renal tubular water absorption.

Among the established causes of acquired DI, the most important are brain tumors, infiltrative granulomatous diseases, head injury, and intracranial surgical trauma (which has become less frequent with the transphenoidal approach to pituitary tumors). In a series of 135 cases of persistent DI reported by Moses and Streeten, 25 percent were idiopathic, 15 percent complicated primary brain tumors, 24 percent were postoperative (mostly after hypophysectomy or surgery for craniopharyngioma), 18 percent were due to head trauma, and fewer than 10 percent were associated with intracranial histiocytosis, metastatic cancer, sarcoidosis, and ruptured aneurysm. Granulomatous infiltration of the base of the brain by sarcoma, eosinophilic granuloma, Letterer-Siwe disease, or Hand-Schüller-Christian disease is a more frequent cause of DI in young patients. Of the primary tumors, glioma, hamartoma and craniopharyngioma, granular cell tumor (choristoma), large chrophobe adenomas, and pinealoma are notable. The primary tumors can present with DI alone, whereas the granulomatous infiltrating processes generally exhibit other systemic manifestations before polydipsia and polyuria appear. Metastatic tumors originating in the lung or breast or leukemic infiltration may also cause DI, sometimes in conjunction with pituitary disturbances and impairment of vision. The mild global hypothalamic dysfunction that often follows brain irradiation for glioma may occasionally include DI as a feature. The most extreme cases of hypothalamic destruction occur in brain death, in which DI is a regular component, although it is not always evident at the time brainstem reflexes are lost.

Pituitary tumors are infrequently associated with DI unless they become massive and invade the stalk of the pituitary and the infundibulum. This anatomic relationship has been substantiated by surgical sections of the stalk for metastatic carcinoma and for retinitis proliferans, which result in DI only if the section is high enough to produce retrograde degeneration of supraoptic neurons.

Among the idiopathic forms of DI, there also exists a congenital type of hypothalamic DI, of which only a small number of familial cases have been described. The disorder is evident at an early age and persists throughout life, owing to a developmental defect of the supraoptic and paraventricular nuclei and smallness of the posterior lobe of the pituitary. This defect has been related in some cases to a point mutation in the vasopressin-neurophysin-glycopeptide gene. It may be combined with other genetic disorders such as diabetes mellitus, optic atrophy, deafness (Wolfram syndrome), and Friedreich ataxia.

Acquired idiopathic DI may occur at any age, most often in childhood or early adult life and more often in males, and by definition has no apparent cause. Other signs of hypothalamic or pituitary disease are lacking in 80 percent of such patients, but steps must be taken to exclude other disease processes by repeating the endocrine and radiologic studies periodically. In some cases of idiopathic DI, there are serum antibodies that react with the supraoptic neurons, raising the question of an autoimmune disorder. In a few such instances, postmortem examination has disclosed a decreased number of neurons in the supraoptic and paraventricular nuclei. Also, anorexia nervosa is often associated with mild DI.

Finally, it should be mentioned that certain drugs used in neurologic practice—for example, carbamazepine—may be the cause of reversible DI (excessive secretion of ADH is more common in relation to this drug), and as mentioned, lithium regularly causes DI, even at times at the upper range of its therapeutic serum concentration.

In all these conditions, the severity and permanence of the DI are determined by the nature of the lesion. In cases of acute onset, three phases have been delineated: first, a severe DI lasting days; then, as the neurohypophysis degenerates, a reduction in severity of DI due to release of stored ADH; and finally a persistent pattern, usually lifelong. The neurohypophysial axons can regenerate, allowing for some degree of recovery even after years.

Diagnosis of DI This is always suggested by the passage of large quantities of dilute urine accompanied by polydipsia and polyuria lasting throughout the night. The last two signs are, of course, obscured in an unresponsive patient, in which case careful measurement of fluid output and input are needed to expose the disorder. The thirst mechanism and drinking usually prevent dehydration and hypovolemia, but if the patient is stuporous or the thirst mechanism is inoperative, severe dehydration and hypernatremia can occur, leading to coma, seizures, and death.

A low urine osmolality and specific gravity are found in DI, in conjunction with high serum osmolality and sodium values. Osmotic dehydration as a cause of the polydipsia-polyuria syndrome, such as occurs with the glycosuria of diabetes mellitus, must, of course, be excluded. A period of 6 to 8 h of dehydration increases urinary osmolality in a person with normal kidneys and neurohypophysis; it is this change in urine concentration that is most useful in the differential diagnosis of polyuria, particularly in distinguishing compulsive water drinkers from those with DI; in the latter group, urinary volume and serum electrolytes normalize with dehydration. Proof that the patient has a central cause of DI and not nephrogenic unresponsiveness to vasopressin is obtained by injecting 5 U of vasopressin (Pitressin) subcutaneously; this will diminish urine output and increase osmolality when there is a central cause of DI. Diagnosis is aided by the radioimmunoassay for plasma ADH; ADH is usually reduced to less than 1.0 pg/mL in patients with central DI (normal, 1.4 to 2.7 pg/mL).

Treatment of DI Vasopressin tannate in oil, synthetic vasopressin nasal spray, and a long-acting analogue of arginine vasopressin (desmopressin, DDAVP) administered by nasal insufflation (10 to 20 mg or 0.1 to 0.2 mL) are used to control chronic DI. The nasal form is generally preferred because of its long antidiuretic action and few side effects. In unconscious patients, aqueous vasopressin, 5 to 10 U given subcutaneously, is effective for 3 to 6 h; DDAVP, 1 to 4 mg subcutaneously, is effective for 12 to 24 h. These drugs must be given repeatedly, guided by urine output and osmolality (we have given these drugs intravenously in critical situations). The brief duration of action of the medication is advantageous in postoperative states and after head injury, for it allows the recognition of recovery of neurohypophysial function and the avoidance of water intoxication. If a longer duration of treatment is anticipated, one uses vasopressin tannate in oil (2.5 U), the action of which persists for 24 to 72 h. In the unconscious patient, great care must
be taken in the acute stages to replace the fluid lost in the urine, but not to the point of water intoxication. These problems can be avoided by matching the amount of intravenous fluids to the urinary volume and by evaluating serum and urine osmolalities every 8 to 12 h. For patients with partial preservation of ADH function, chlorpropamide, clofibrate, or carbamazepine can be used to stimulate release of the hormone.

Syndrome of Inappropriate Antidiuretic Hormone (SIADH) Secretion As mentioned, blood volume and osmolality are normally maintained within narrow limits by the secretion of ADH and the thirst mechanism. A reduction in osmolality of even 1 percent stimulates osmoreceptors in the hypothalamus to decrease ADH and to suppress thirst and drinking; increased osmolality and reduced blood volume do the opposite. Normally, blood osmolality is about 282 mmol/kg and is maintained within a very narrow range. Release of ADH begins when it reaches 287 mmol/kg (osmotic threshold). At this point, plasma ADH levels are 2 pg/mL and increase rapidly as the osmolality rises. The response of ADH secretion to hyperosmolality is not the same for all plasma solutes; in contrast to hypernatremia, for example, hyperosmolality induced by elevations in urea nitrogen or endogenous glucose produce minimal or no elevations in ADH.

Derangement of this delicately regulated mechanism, taking the form of dilutional hyponatremia and water retention without edema, is observed under a variety of clinical circumstances in which the plasma ADH is above normal or inappropriately normal despite plasma hypo-osmolality. The term inappropiate secretion of antidiuretic hormone (SIADH) was applied to this syndrome by Schwartz and Bartter because of its similarity to that produced in animals by the chronic administration of ADH. The same syndrome can arise from ectopic production of the hormone by tumor tissue. In such cases, the thirst mechanism is not inhibited by decreased osmolality, and continued drinking further increases blood volume and reduces its solute concentration; ADH levels are found to be persistently elevated. The physiologic hallmarks of this condition are a concentrated urine, usually with an osmolality above 300 mosm/L, and low serum osmolality and sodium concentrations. Because of the dilutional effects, urea nitrogen and uric acid are reduced in the blood and serve as markers for excessive total body water. Tissue edema is not seen because sodium excretion in the urine is maintained by suppression of the renin-angiotensin system and by an increase in atrial natriuretic peptide secretion (see below).

SIADH is observed frequently with a variety of cerebral lesions (infarct, tumor, hemorrhage, meningitis, encephalitis) that do not involve the hypothalamus directly and with many types of local hypothalamic disease (trauma, surgery, vascular lesions). In most cases it tends to be a transient feature of the underlying illness. The acute dysautonomia of Guillain-Barré syndrome is a common cause of SIADH, and hyponatremia is particularly likely to occur in such patients being ventilated mechanically. The increased thoracic pressure induced by positive-pressure ventilation promotes SIADH in susceptible patients. Acute porphyric episodes have the same effect. Neoplasms, particularly oat-cell tumors and sometimes inflammatory lesions of the lung, may elaborate an ADH-like substance, and certain drugs—such as carbamazepine, chlorpromazine, chlorothiazide, chlorpropamide, clofibrate, nonsteroidal anti-inflammatory agents, and vincristine—also stimulate ADH release and may lead to hyponatremia. In some cases, no cause or associated disease is apparent.

A fall in serum sodium to 125 meq/L usually has no apparent clinical effects, although signs of an associated neurologic disease, such as a previous stroke or a subdural hematoma, may worsen. Sodium levels of less than 120 meq/L are attended by nausea and vomiting, inattentiveness, drowsiness, stupor, and generalized seizures. There may be asterixis. As is characteristic of most metabolic encephalopathies, the more rapid the decline of the serum sodium, the more likely there will be accompanying neurologic symptoms.

Treatment of SIADH The rapid restitution of serum sodium to normal or above-normal levels carries a risk of producing central pontine myelinolysis (see page 973). Our usual procedure in patients with serum sodium concentrations of 117 to 125 meq/L is to slowly correct the sodium concentration by restricting water to 400 to 800 mL/day and to verify the desired urinary loss of water by checking the patient’s weight and serum sodium until it reaches the lower range of 130 meq/L. If there is drowsiness, confusion, or seizures that cannot be confidently attributed to the underlying neurologic illness or if the serum sodium is in the range of 100 to 115 meq/L, isotonic or 3% NaCl should be infused over 3 to 4 h and furosemide 20 to 40 mg administered to prevent fluid overload. A safe clinical rule is to raise the serum sodium by no more than 12 meq/L in the first 24 h and by no more than 20 meq/L in 48 h in order to prevent myelinolysis.

Neurogenic (Cerebral) Salt Wasting A moderate reduction in the serum sodium concentration is a common finding in patients with acute intracranial diseases and postoperatively in neurosurgical patients. Originally it was described as a “cerebral salt-wasting” syndrome by Peters and colleagues and later was erroneously identified with the then newly described Schwartz-Bartter syndrome of SIADH. In recent years it has again come to be recognized as being due to natriuresis and not to water retention caused by ADH secretion. Later, as Nelson and colleagues demonstrated, neurosurgical patients with hyponatremia and ostensibly with SIADH showed, instead, a reduction in blood volume, suggesting sodium loss rather than water retention. This distinction has important clinical implications, because the use of fluid restriction with the intention to treat SIADH can have disastrous results if a state of volume contraction exists from salt wasting. One leading hypothesis concerning the mechanism of hyponatremia in these cases is secretion of another oligopeptide, atrial natriuretic factor (ANF), that is found mainly in the walls of the cardiac atria but also in neurons surrounding the third ventricle in the anteroventral hypothalamic region. Physiologically, ANF activity opposes that of ADH in the kidney tubules and also has a potent inhibitory effect on ADH release from the hypothalamus; i.e., it causes a natriuresis (see review by Samson). ANF, like some other neural peptides, is secreted in bursts, and the natriuresis is evident only if total urinary sodium content is measured over many hours or days.

The role of ANF in causing the hyponatremia that follows subarachnoid hemorrhage is controversial (see Wijdicks et al and Diringer et al for opposing views), but it is our experience that the hyponatremia in this condition is the result mainly of salt loss, not water retention. Because fluid restriction after subarachnoid hemorrhage may precipitate cerebral ischemia from vasospasm, the proper approach is to maintain intravascular volume with intravenous fluids and to correct hyponatremia by infusion of normal saline.

In addition to head trauma, salt wasting has also been reported with cerebral tumors, after pituitary surgery, and in the dysautonomia of Guillain-Barré syndrome, conditions that have also been associated at times with SIADH. As already stated, in each of these
disorders, should the patient be hyponatremic, it is desirable to determine the intravascular volume and the urine sodium output before instituting treatment.

Other Disturbances of ADH and Thirst Conditions have been described in which the osmoreceptor control of ADH and of thirst appear to be dissociated. As reported by Hayes and coworkers, one of our colleagues’ patients repeatedly developed severe hyponatremia (levels as high as 180 to 190 meq/L), at which time he became confused and stuporous. Although the patient was able to initiate a release of ADH, his thirst mechanism was nonfunctional. Only when the patient was compelled to drink water at regular intervals did his serum sodium fall. Robertson and others have described similar cases with abnormalities of thirst. These have been reported under the title of “central” or “essential” hyponatremia.

Pituitary Insufficiency Loss of function of the anterior pituitary gland may result from disease of the pituitary itself or from hypothalamic disease. In either event, it leads to a number of clinical abnormalities, each predicated on the deficiency of one or more hormones that depend on the pituitary trophic factors described earlier. The condition of panhypopituitarism represents the more serious illness in that it requires supplementation with multiple hormones. Hypopituitarism may have its onset in childhood, either as an inherited process that affects individual or multiple hormones or as a secondary process associated with the premature development of secondary sexual characteristics and menstruation, one seeks other evidence of hypothalamic disease as well as an estrogen-secreting ovarian tumor.

A hamartoma of the hypothalamus (part of von Recklinghausen disease or of polyostotic fibrous dysplasia) is a leading cause of precocious puberty in both boys and girls; in a number of such cases, so-called gelastic seizures have been conjoined (Breningstall, see page 278). Neurologic study entails computed tomography (CT) and MRI imaging of the hypothalamus, ovaries, and adrenals.

Adiposogenital Dystrophy (Froehlich Syndrome) Under this title, in 1901, Froehlich first described the association of obesity and gonadal underdevelopment. He related the disorder to a pituitary tumor. But a few years later, Erdheim recognized that the same syndrome could be a manifestation of a lesion (a suprasellar cyst in his case) involving or restricted to the hypothalamus. Later it was determined that obesity and hypogonadism could occur together or separately and were often combined with a loss of vision and unprovoked rage, aggression, or antisocial behavior. Diabetes insipidus may be added. In some patients, the clinical state is characterized by abulia, apathy, and reduced verbal output. The usual causes of the Froehlich syndrome are craniopharyngioma, adamantinoma, and glioma, but many other tumors have been reported (pituitary adenoma, cholesteatoma, lipoma, meningioma, glioma, angiosarcoma, and chordoma). The condition bears clinical similarities to the Prader-Willi syndrome, in which hypothalamic abnormalities are not found (page 864).

Hypothalamic Disorders Associated with Alterations in Weight Precise neuroanatomic studies have localized a satiety center in the ventromedial nucleus of the hypothalamus and an appetite center in the ventrolateral nucleus. Lesions in the lateral hypothalamus may result in a failure to eat and, in the neonate, failure to thrive; lesions in the medial hypothalamus, in overeating and obesity. Bray and Gallagher, who analyzed eight cases of the latter type, concluded that the critical lesion was a bilateral destruction of the ventromedial regions of the hypothalamus. Most of the reported cases of this type have been due to tumors, particularly craniopharyngioma, and some to trauma, inflammatory disease, and hydrocephalus (Suzuki et al). In a case that was subject to clinicopathologic correlation, Reeves and Plum found that a hamartoma had destroyed the medial eminence and the ventromedial nuclei bilaterally but spared the lateral hypothalamus. Hyperphagia and rage reactions were the main clinical features; the associated polydipsia and polyuria were due to extension of the tumor to the anterior hypothalamus. It is evident that in only a tiny fraction of persons can obesity be traced to a hypothalamic lesion. Of overriding importance are genetic factors, such as the number of lipocytes that one inherits and their ability to store fat.

Precocious Puberty This term refers to the abnormally early onset of androgen secretion and spermatogenesis in boys and of estrogen secretion and cyclic ovarian secretion in girls. It is associated with the premature development of secondary sexual characteristics. The occurrence of precocious puberty always calls for a neurologic as well as an endocrine investigation. In the male, one seeks for evidence of a teratoma of the pineal gland or mediastinum or an androgenic tumor of the testes or adrenals. In the female with early development of secondary sexual characteristics and menstruation, one seeks other evidence of hypothalamic disease as well as an estrogen-secreting ovarian tumor.

A rare disorder of infants has been described under the title of diencephalic syndrome. Progressive and ultimately fatal emaciation (failure to thrive), despite normal or near-normal food intake, in an otherwise alert and cheerful infant is the main clinical feature. The lesion has usually proved to be a low-grade astrocytoma of the anterior hypothalamus or optic nerve (Burr et al). Extrahypothalamic parts of the brain, if diseased, may also be associated with increased food-seeking behavior, food ingestion, and weight gain. Examples are involvement of limbic structures, as in the Klüver-Bucy syndrome (page 448) and basal frontal lobe lesions leading to gluttony.

Anorexia Nervosa and Bulimia The special syndromes called anorexia nervosa and bulimia have been difficult to classify and are mentioned in this chapter only because they are associated with
alterations in several hypothalamic functions, including appetite, temperature control, and menstruation. In all likelihood, these alterations are not the result of a primary dysfunction of hypothalamic nuclei but are secondary to the extreme weight loss, which is the primary feature of the disease. However, a causal link between these idiopathic diseases and hypothalamic dysfunction has been suggested by the rare patients with anorexia nervosa who were later found to have hypothalamic tumors (Bhanji and Mattingly, Berek et al., and Lewin et al.).

Anorexia nervosa and bulimia are probably best regarded as disorders of behavior, in this case an obsession with thinness; they are therefore discussed with the psychiatric disorders (see page 1304). But the developmental nature of the disease (arising in early adolescence), its virtual absence in men, and the hypothalamic alterations mentioned above do not allow the dismissal of a primary disorder of the brain’s appetite centers.

**Abnormalities of Growth** Presumably, in most instances of growth retardation, there is a deficiency of GHRH or of GH per se. In the Prader-Willi syndrome (obesity, hypogonadism, hypotonia, mental retardation, and short stature), Bray and Gallagher found the deficiency to be one of GHRH. In certain congenital and developmental diseases, the hypothalamus appears to be incapable of releasing GH. This appears to be the case, in the de Morsier septo-optic defect of the brain (median facial cleft, cavum septum pel- lucidum, optic defect), Stewart and colleagues found an isolated deficiency of GH. In children with idiopathic hypopituitarism in whom stunting of growth is associated with other endocrine abnormalities, the deficiency is probably in the synthesis or release of GHRH. In some dwarfs (Laron dwarf, Seckel bird-headed dwarf), there are extremely high levels of circulating GH, suggesting either a defect in the GH molecule or an unresponsiveness of target organs. Many patients with the more severe forms of mental retardation are subnormal in height and weight, but the explanation for this has not been ascertained. It has not been reducible to changes in the level of GHRH or GH.

Of course, the vast majority of unusually short children who are otherwise healthy do not have a recognizable defect in GH or GHRH. Often their parents are short. The therapeutic use of GH in such children is a controversial matter. The hormone effects a spurt in growth during the first year of its administration, but whether it significantly influences growth in the long term is still under investigation. There is concern about the risk of transmitting prion abnormalities, the deficiency is probably in the synthesis or release of GHRH. The possibility of an ectopic source of GH must also be considered. The mentally retarded individuals with gigantism described by Sotos and coworkers were found to have no abnormalities of GHRH, GH, or somatomedin.

**Disturbances of Temperature Regulation** Bilateral lesions in the anterior parts of the hypothalamus, specifically of temperature-sensitive neurons in the preoptic area, may result in *hyperthermia*. The heat-dissipating mechanisms of the body, notably vasodilation and sweating, are impaired. This effect has followed operations or other trauma in the region of the floor of the third ventricle but we have seen it most often after massive rupture of an anterior communicating artery aneurysm. The temperature rises to 41°C (106°F) or higher and remains at that level until death some hours or days later, or it drops abruptly with recovery. Acetylsalicylic acid has little effect on central hyperthermia; the only way to control it is by active evaporative cooling of the body while administering sedation. A less dramatic example of the loss of natural circadian temperature patterns is seen in patients with postoperative damage in the suprachiasmatic area (Cohen and Albers) and suprachiasmatic metastasis (Schwartz et al.). These types of lesions are invariably associated with other disorders of intrinsic rhythmicity, including sleep and behavior. It should be emphasized, however, that instances of “central fever” are rare, and unexplained fever of moderate degree should not be attributed to a putative brain lesion.

Hyperthermia is also part of the *malignant hyperthermia* syndrome, in which, in a small number of cases, there is an inherited (autosomal dominant) susceptibility to develop hyperthermia and muscle rigidity in response to inhalation anesthetics and skeletal muscle relaxants (page 1272). It has been found to be due in these few instances to a defective ryanodine receptor. Closely related is the *neuroleptic malignant syndrome*, which is the result of an idiosyncratic reaction to neuroleptic drugs (page 1025). Wolff and colleagues have described a syndrome of *periodic hyperthermia*, associated with vomiting, hypertension, and weight loss and accompanied by an excessive excretion of glucocorticoids; the symptoms had no apparent explanation, although there was a symptomatic response to chlorpromazine.

Lesions in the posterior part of the hypothalamus have had a different effect; i.e., they often produce *hypothermia* (a persistent temperature of 35°C or less) or *poikilothermia* (equilibration of body and environmental temperatures). The latter may pass unnoticed unless the patient’s temperature is taken after lowering and raising the room temperature. Somnolence, confusion, and hypotension may be associated. *Spontaneous periodic hypothermia*, probably first described by Gowers, has been found in association with a cholesteatoma of the third ventricle (Penfield) and with agenesia of the corpus callosum (Noel et al.). Episodically, there are symptoms of autonomic disturbance—salivation, nausea and vomiting, vasodilation, sweating, lacrimation, and bradycardia; the rectal temperature may fall to 30°C and seizures may occur. Penfield referred to these attacks incorrectly as “diencephalic epilepsy” (page 466). Between attacks, which last a few minutes to an hour or two, neurologic abnormalities are usually not discernible and temperature regulation is normal.

*Chronic hypothermia* is a more familiar state than hyperthermia, being recorded in cases of hypothyroidism, hypoglycemia, and uremia; after prolonged immersion or exposure to cold; and in cases of intoxication with barbiturates, phenothiazines, or alcohol. It tends to be more frequent among elderly patients, who are often found to have an inadequate thermoregulatory mechanism.

**Cardiovascular Disorders with Hypothalamic Lesions** Ranson demonstrated a number of autonomic effects upon stimulation of the hypothalamus; these effects as well as hypertension were recorded in Penfield’s case of “diencephalic epilepsy,” mentioned above. Since Byer and colleagues’ description of large, upright T waves and prolonged QT intervals in patients with stroke, it has been appreciated that acute lesions of the brain—particularly sub-
arachnoid hemorrhage and head trauma—may be accompanied by changes in the electrocardiogram (ECG) as well as by supraventricular tachycardia, ectopic ventricular beats, and ventricular fibrillation. Most of the same effects can be induced by very high levels of circulating norepinephrine and corticosteroids. Considering the numerous catastrophic lesions of the brain as well as extreme emotional states that can provoke arrhythmias and other changes in the ECG, the hypothalamus, with its limbic connections and ability to mount a massive sympathoadrenal discharge, is the likely source of these autonomic changes. Cropp and Manning found that the changes seen in the ECG, particularly “cerebral T waves” and other reversible repolarization abnormalities, could occur almost instantaneously (too quickly for attribution to circulatory factors) during surgery for a cerebral aneurysm. Again, the hypothalamus is implicated, but as yet no direct evidence links this structure to direct cardiac control.

Gastric Hemorrhage In experimental animals, lesions placed in or near the tuberal nuclei induce superficial erosions or ulcerations of the gastric mucosa in the absence of hyperacidity (Cushing ulcers). Gastric lesions of similar type are seen in patients with several types of acute intracranial disease (particularly subdural hematoma and other effects of head injury, cerebral hemorrhages, and tumors). In seeking causative lesions, as in patients dying with cerebral changes, one searches in vain for a lesion in the various hypothalamic nuclei. A functional disorder in this region is nonetheless suspected.

“Neurogenic” Pulmonary Edema Following the original observations by Maire and Patton in humans, numerous cases of massive and often fatal pulmonary edema have been described in relation to catastrophic intracranial lesions—head injury, subarachnoid and intracerbral hemorrhage, bacterial meningitis, and status epilepticus being the usual ones. A sudden elevation in intracranial pressure is involved in most cases, usually accompanied by a brief bout of extreme systemic hypertension but without obvious left ventricular failure—which is one reason the pulmonary edema has been attributed to a “neurogenic” rather than a cardiogenic cause. Also, it has been shown that experimental lesions in the caudal hypothalamus are capable of producing this type of pulmonary edema, but almost always with the interposed event of brief and extreme systemic hypertension.

Both the pulmonary edema and hypertensive response can be prevented by sympathetic blockade at any level, suggesting that the adrenergic discharge and the hypertension it causes are essential for the development of pulmonary edema. The rapid rise in vascular resistance and systemic blood pressure is similar to the pressor reaction obtained by destruction of the nucleus of the tractus solitarius, as described in Chap. 26, making understandable the few instances of neurogenic edema that have followed acute lesions in the medullary tegmentum [as was seen in one of our patients (Brown et al)]. At issue is whether the hypothalamus exerts a direct sympathetic influence on the pulmonary vasculature, allowing a leakage of protein-rich edema fluid, or if the edema is the result of sudden and massive overloading of the pulmonary circulation by a shift of fluid from the systemic vasculature. The latter theory, essentially one of momentary right heart failure, is currently favored but does not explain all aspects of the syndrome. Likewise, the role of circulating catecholamines and adrenal steroids has not been fully elucidated. These issues have been summarized in the text on neurologic intensive care by Ropper and colleagues.

Disorders of Consciousness and Personality Since Ranson’s original experimental work in monkeys, it has been appreciated that acute lesions in the posterior and lateral parts of the hypothalamus may be associated with stupor although it has always been difficult to determine the precise structures that were involved. One can be certain that permanent coma from small lesions in the diencephalon may occur in the absence of any changes in the hypothalamus, and, conversely, that chronic hypothalamic lesions may be accompanied by no more than drowsiness or confusion or no mental change at all. In one of our cases, involving an infundibuloma entirely confined to the hypothalamus, the patient lay for weeks in a state of torpor, drowsy and confused. His blood pressure was low, his body temperature was 34 to 35°C, and he had diabetes insipidus. When aroused, he was aggressive, like the patient of Reeves and Plum (see above). Among the cases of acquired changes in personality and sleep patterns from ventral hypothalamic disease that we have seen, a few have been impressive because of a tendency to a hypomanic, hypervigilant state with insomnia, lasting days on end, and an impulseness and disinhibition suggestive of involvement of the frontal connections to the hypothalamus. In one recent case we examined following removal of a craniopharyngioma, a delirious, agitated state lasted 3 weeks during which the patient’s attention could not be captured for even a moment. These and other cognitive disorders with hypothalamic lesions are difficult to interpret and are usually transient. Often the lesions are acute and involve adjacent areas, making it impossible to attribute them to the hypothalamus alone.

Periodic Somnolence and Bulimia (Kleine-Levin Syndrome) Kleine in 1925 and Levin in 1936 described an episodic disorder characterized by somnolence and overeating. For days or weeks, the patients, mostly adolescent boys, sleep 18 or more hours a day, awakening only long enough to eat and attend to toilet needs. They appeared dull, often confused, and restless and were sometimes troubled by hallucinations. The hypothalamus has been implicated on the basis of these symptoms but without definite pathologic confirmation. We have had some experience with patients having this disorder; a further discussion can be found on page 344 in the chapter on Sleep and Its Abnormalities.

Neuroendocrine Syndromes Related to the Adrenal Glands

Cushing Disease and Cushing Syndrome The clinical features of Cushing disease, first described in Cushing’s classic monograph in 1932, are familiar to everyone in medicine: truncal obesity with reddish purple cutaneous striae over the abdomen and other parts, dryness and pigmentation of the skin and fragility of skin vessels, excessive facial hair and baldness, cyanosis and motting of the skin of the extremities, osteoporosis and thoracic kyphosis, proximal muscular weakness, hypertension, glycosuria, and a number of psychologic disturbances. Adrenal hyperplasia secondary to a bauxititis adenoma of the pituitary (pituitary basophilia was Cushing’s term) was the established pathologic in Cushing’s cases. It is to the pituitary form of hyperadrenalism that the term Cushing disease has been applied. But the same combination of abnormalities may be associated with chronically increased production of cortisol from a primary adrenal tumor, ectopic production of ACTH by carcinoma of the lung or other carcinomas, and most commonly, with the prolonged administration of glucocorticoids (prednisone, methylprednisolone, or ACTH). For these latter conditions, all but
the last being associated with secondary adrenal hyperplasia, the term Cushing syndrome is appropriate. Some components of the syndrome may be lacking or less conspicuous than in florid Cushing disease; diagnosis is then facilitated by measurements of ACTH and cortisol in the blood and urine. Cushing syndrome of ectopic type tends to differ clinically from primary pituitary Cushing disease with respect to its more rapid development and to greater degrees of skin pigmentation, hypokalemia, hypertension, and glycosuria. Plasma concentrations of ACTH exceed 50 µg/dL in the ectopic type and are not suppressed by dexamethasone administration.

In Orth’s review of 630 cases of Cushing syndrome of endogenous cause, 65 percent were due to hyperpituitarism (Cushing disease), 12 percent to an ectopic production of ACTH, 10 percent to an adrenal adenoma, and 8 percent to adrenal carcinoma.

In Cushing disease, hyperplasia of pituitary cells or a better-defined basophil or chromophobe adenoma produce ACTH, which stimulates the adrenals. Unlike the usual pituitary tumors, the corticotroph (basophil) type are usually microadenomas (<1 cm) and enlarge the sella in only 20 percent of cases. However, it is now appreciated by MRI or high-resolution CT through the sella, that either micro- or macroadenomas are the cause in about 80 percent of cases. There are only a few cases in which a hypothalamic tumor such as a gangliocytoma has caused Cushing syndrome.

For diagnostic purposes, measurement of the excretion of cortisol over 24 h in the urine is the most expeditious test and superior to serum sampling because of fluctuations in the serum levels of ACTH. If a 24-h urine collection is not feasible, it is advisable to obtain two or three daily determinations, since the values may vary from day to day in Cushing syndrome and patients are frequently unable to save all their urine. The normal value for urinary excretion of cortisol is approximately 12 to 40 mg in 24 h, but some assays that measure additional metabolites of the hormone may allow normal values up to 100 mg. This should be followed by low- or high-dose dexamethasone suppression testing. A test using high doses of dexamethasone (2 mg every 6 h orally for 2 days, or a single dose of 8 mg at midnight) is the most dependable screening method for separating Cushing disease from ectopic secretion of ACTH. As mentioned, in the latter condition, the urinary excretion of cortisol is not suppressed by the administration of dexamethasone, whereas there is a reduction of 90 percent in urinary excretion in 60 to 70 percent of patients with Cushing disease.

Treatment is governed by the cause of the syndrome. A pituitary adenoma, if not extending out of the sella and encroaching on the optic chiasm (microadenoma), is ideally treated by transsphenoidal pituitary microsurgery, as discussed in Chap. 31. The alternative is focused proton beam or gamma radiation, but the long latency of response to these forms of treatment, 6 months or more, makes them less desirable. If such indirect methods of treatment are used, hypercortisolism may be suppressed in the interim by adrenal enzyme inhibitors such as ketoconazole, metapyrone, or aminoglutethimide. The rate of cure for pituitary microadenoma by transsphenoidal surgery approaches 80 percent, although operative complications—CSF leakage, transient diabetes insipidus, visual abnormalities, meningitis—occur in as many as 10 percent of patients. In about 20 percent of patients, removal of the tumor is incomplete and symptoms persist or recur. In such circumstances reoperation is often undertaken, with total excision of the gland and a subsequent requirement for extensive hormone replacement in many cases. As an alternative, radiotherapy may be used after failed surgery. If there is an urgent need to suppress the effects of hypercortisolism, bilateral adrenalectomy is effective but has obvious limitations.

Depending on the functional status of the pituitary after any mode of successful treatment, replacement therapy may be needed for a variable period.

Adrenocortical Insufficiency (Addison Disease) The classic form of adrenal insufficiency, described by Addison in the nineteenth century, is due to primary disease of the adrenals. It is characterized by pigmentation of the skin and mucous membranes, nausea, vomiting, and weight loss as well as muscle weakness, languor, and a tendency to faint. Since Addison’s time, hypotension, hyperkalemia, hyponatremia, and low serum cortisol concentrations have come to be recognized as important laboratory features.

In former times, the most common cause of primary adrenal disease was tuberculosis. Now, most cases are designated as idiopathic and thought to represent an autoimmune disorder, often associated with Hashimoto thyroiditis and diabetes mellitus and rarely with other polyglandular autoimmune endocrine disorders. A less frequent cause is a hereditary metabolic disease of the adrenals—in combination with a demyelinating disease of brain, spinal cord, and nerves and occurring predominantly in males (adrenoleukodystrophy; see page 836). In primary adrenal disease, plasma concentrations of cortisol are low, in response to which the concentrations of ACTH rise. Adrenal insufficiency of whatever cause is a life-threatening condition; there is always a danger of collapse and even death, particularly during periods of infection, surgery, injury, and the like. Lifelong replacement therapy is usually required, with a glucocorticoid (cortisone, 25 to 50 mg, or prednisone, 7.5 to 15 mg daily) and a mineralocorticoid, such as fludrocortisone acetate (Florinef), 0.05 to 0.2 mg daily.

When adrenal insufficiency is secondary to disease of the pituitary, ACTH is low or absent and cortisol secretion is markedly reduced, but aldosterone levels are sustained. Hyperpigmentation is notably absent; it is the elevation of ACTH that causes melanoderma, such as occurs, for example, in patients subjected to bilateral adrenalectomy. Hypothalamic lesions, principally involving the paraventricular nuclei, may also cause adrenal insufficiency, but less frequently than do pituitary lesions.

PART 3

GROWTH AND DEVELOPMENT OF THE NERVOUS SYSTEM AND THE NEUROLOGY OF AGING
This page intentionally left blank.
In this chapter and the next we consider the effects of growth, maturation, and aging on the nervous system. These are elaborated in some detail because certain aspects of neurologic diseases are meaningful only when viewed against the background of these natural age-linked changes. Developmental diseases of the nervous system, i.e., malformations and diseases that are acquired in the intrauterine period of life, are considered in Chap. 38.

**TIME-LINKED SEQUENCES OF NORMAL DEVELOPMENT**

The establishment of a biologic time scale of human development requires observation, under standardized conditions, of a large number of normal individuals of known ages and testing them for measurable items of behavior. Because of individual variations in the tempo of development, it is equally important to study the growth and development of any one individual for a prolonged period. If these observations are to be correlated with stages of neuroanatomic development, the clinical and morphologic data must be expressed in units that are comparable. Early in life, age periods are difficult to ascertain because of the special difficulty in fixing the time of conception. The average human gestational period is 40 weeks (280 days), but birth may occur with survival as early as 28 or as late as 49 weeks (a time span of almost 5 months), and the extent of nervous system development will vary accordingly.

After birth, any given item of behavior or structural differentiation must always have two reference points: (1) to a particular item of behavior that has already been achieved, and (2) to units of chronologic time or duration of life of the organism. The chronologic or biologic scale assumes special significance in early prenatal life. During that period development proceeds at such a rapid pace that small units of time weigh heavily and the organism appears to change literally day by day. In infancy, the tempo of development slows somewhat but is still very rapid in comparison with later childhood.

The neurologist will find it advantageous to organize his knowledge of normal development and disease around the timetables for human growth and development listed in Tables 28-1 and 28-2. In addition, the last decade has brought startling advances in the understanding of the genetic and molecular control of neural development. That topic is beyond the scope of this chapter, although the important subject of the mutations relevant to the developmental diseases of the nervous system are considered in Chap. 38.

**Neuroanatomic Bases of Normal Development**

A large body of knowledge has accumulated concerning the functional and structural status of the nervous system during each successive period of life. This information is reviewed briefly in the following paragraphs and is summarized in Table 28-2. It must be kept in mind that development of the nervous system does not proceed stepwise, from one period to the next, but is continuous from conception to maturity. The sequences of development are much the same in all infants, although the rate may vary. Any given behavioral function, in order to be expressed, must await the development of its neural substrate. Furthermore, at any given moment in development, several measurable functions appear in parallel, and it is often their dissociation that acquires clinical significance.

**Embryonal and Fetal Periods** What we know of the nervous system in the germinal and embryonal periods has been derived from the study of a relatively small number of abortuses that have come into the hands of anatomists. Neuroblastic differentiation, migration, and neuronal multiplication are already well under way in the first 3 weeks of embryonic life. The control of each of these phases (and, later, of connectivity of neurons) is determined by the genome of the organism. Primitive cells destined to become neurons originate in or close to the neuroepithelium of the neural tube. These cells proliferate at an astonishingly rapid rate (250,000 per minute, according to Cowan) for a circumscribed period (several days to weeks). They become transformed into bipolar neuroblasts, which migrate in a series of waves toward the marginal layer of what is to become the cortex of the cerebral hemispheres. The first glial cells also appear very early and provide the scaffolding along

which the neuroblasts move. Each step in the differentiation and migration of the neuroblasts proceeds in an orderly fashion, and one stage progresses to the next with remarkable precision. The process of migration is largely completed by the end of the fifth fetal month but continues at a much slower rate up to 40 weeks of gestation, according to the classic studies of Conel and of Rabinowicz. Since the migration of most neurons involves postmitotic cells, the cerebral cortex by this time has presumably acquired its full complement of nerve cells, numbered in the many billions. This concept has been revised in recent years with the discovery of active stem cells in the adult brain that generate neurons in the hippocampal formation and in the subventricular matrix zones, giving rise to olfactory neurons in the adult brain (see Kempermann and Alvarez-Buylla and Garcia-Verdugo). Actually, we have little idea of the number of nerve cells in the cerebral and cerebellar cortices at different ages. More are formed than survive, since programmed cell death (apoptosis) constitutes an important phase of development.

Within a few months of midfetal life, the cerebrum, which begins as a small bihemispheric organ with hardly a trace of surface indentation, evolves into a deeply sulcated structure. Every step in the folding of the surface to form fissures and sulci follows a temporal pattern of such precision as to permit a reasonably accurate estimation of fetal age by this criterion alone. The major sylvian, rolandic, and calcarine fissures take on the adult configuration during the fifth month of fetal life, the secondary sulci in the sixth and seventh months, and the tertiary sulci—which vary from one individual to another—in the eighth and ninth months (see Fig. 28-1 and Table 28-2).

Concomitantly, subtle changes in neuronal organization are occurring in the cerebral cortex and central ganglionic masses. Involved here are the processes of synaptogenesis and axonal path-
finding. Neurons become more widely separated as differentiation proceeds, owing to an increase in the size and complexity of dendrites and axons and enlargement of synaptic surfaces (Fig. 28-2). The cytoarchitectural patterns that demarcate one part of the cerebral cortex from another are already in evidence by the 30th week of fetal life and become definitive at 40 weeks and in succeeding months. As the maturational process of cortical neurons proceeds, the patterns of neuronal organization in different regions of the brain (motor, premotor, sensory and striate cortices, Broca and Wernicke areas) continue to change.

Myelination provides another index of the development and maturation of the nervous system and is believed to be related to the functional activity of the fiber systems. The acquisition of myelin sheaths by the spinal nerves and roots by the 10th week of fetal life is associated with the beginning of reflex motor activities. Segmental and intersegmental fiber systems in the spinal cord myelinate soon afterward, followed by ascending and descending fibers to and from the brainstem (reticulospinal, vestibulospinal). The acoustic and labyrinthine systems stand out with singular clarity in myelin-stained preparations by the 28th to 30th weeks, and the spinocerebellar and dentatorubral systems by the 37th week (Fig. 28-3).

**Neonatal Period and Infancy** After birth, the brain continues to grow dramatically. From an average weight of 375 to 400 g at birth (40 weeks), it reaches about 1000 g by the end of the first postnatal year. Glial cells (oligodendrocytes and astrocytes) derived from the matrix zones continue to divide and multiply during the first 6 months of postnatal life. The visual system begins to myelinate about the 40th gestational week; its myelination cycle proceeds rapidly, being nearly complete a few months after birth. The corticospinal tracts are not fully myelinated until halfway through the second postnatal year. Most of the principal tracts are myelinated by the end of this period. In the cerebrum, the first myelin is seen at 40 weeks in the posterior frontal and parietal lobes, and the occipital lobes (geniculocalcarine tracts) myelinate soon thereafter. Myelination of the anterior frontal and temporal lobes occurs later, during the first year of postnatal life. By the end of the second year, myelination of the cerebrum is largely complete (Fig. 28-3). These steps in myelination can be followed by magnetic resonance im-
Childhood, Puberty, and Adolescence  Growth of the brain continues, at a much slower rate than before, until 12 to 15 years, when the average adult weight of 1230 to 1275 g in females and 1350 to 1410 g in males is attained. Myelination also continues slowly during this period. Yakovlev and Lecours, who re-examined Flechsig's classic findings on the ontogeny of myelination (the term Flechsig's myelinogenic cycle is still used), traced the progressive myelination of the middle cerebellar peduncle, acoustic radiation, and bundle of Vicq d'Azyr (mammillothalamic tract) beyond the third postnatal year; the nonspecific thalamic radiations continued to myelinate beyond the seventh year and fibers of the reticular formation, great cerebral commissures, and intracortical association neurons to at least the 10th year and beyond (Fig. 28-3). These investigators noted that there was an increasing complexity of fiber systems through late childhood and adolescence and perhaps even into middle adult life. Similarly, in the extensive studies of Conel and Rabinowicz, depicting the cortical architecture at each year from mid–fetal life to the 20th year, the dendritic arborizations and cortical interneuronal connections were observed to increase progressively in complexity; the “packing density” of neurons, i.e., the number of neurons in any given volume of tissue increases through the age of approximately 15 months and then decreases (Fig. 28-2).

Interesting questions are (1) whether neurons begin to function only when their axons have acquired a myelin sheath; (2) whether myelination is under the control of the cell body, the axon, or both; and (3) whether the classic myelin stains yield sufficient information as to the time of onset and degree of the myelination process. At best these correlations can be only approximate. It seems likely that systems of neurons begin to function before the first appearance of myelin, as shown in conventional myelin stains. These correlations need to be restudied, using more delicate measures of function and finer staining techniques, as well as the techniques of quantitative biochemistry and phase and electron microscopy.

Physiologic and Psychologic Development

Neural Development in the Fetus  The human fetus is capable of a complex series of reflex activities, some of which appear as early as 5 weeks of postconceptional age. Cutaneous and proprioceptive stimuli evoke slow, generalized, patterned movements of the head, trunk, and extremities. More discrete movements appear to differentiate from these generalized activities. Reflexes subserving blinking, sucking, grasping, and visceral functions, as well as tendon and plantar reflexes, are all elicitable in late fetal life. They seem to develop along with the myelination of peripheral nerves, spinal roots, spinal cord, and brainstem. By the 24th week of gestation, the neural apparatus is functioning sufficiently well to give the fetus some chance of survival should birth occur at this time. However, most infants fail to survive birth at this age, usually ow-
Development during the Neonatal Period, Infancy, and Early Childhood. At term, effective sucking, rooting, and grasping reactions are present. The infant is able to swallow and cry, and the startle reaction (Moro reflex, page 505) can be evoked by loud sound and sudden extension of the neck. Support and stepping movements can be demonstrated by placing the infant on its feet, and incuration of the trunk by stroking one side of the back. Also present at birth is the placing reaction, wherein the foot or hand, brought passively into contact with the edge of a table, is lifted automatically and placed on the flat surface. These neonatal automatisms depend essentially on the functioning of the spinal cord, brainstem, and possibly diencephalon and pallidum. The Apgar score, a universally used but somewhat imprecise index of the well-being of the newborn infant, is in reality a numerical rating of the adequacy of brainstem-spinal mechanisms (breathing, pulse, color of skin, tone, and responsiveness) (Table 28-3).

Studies of local cerebral glucose metabolism by positron emission tomography (PET) have provided interesting information about the functional maturation of the brain. There are remarkable differences between the newborn and the mature individual. Neonatal values, adjusted for brain weight, are only one-third those of the adult; except for the primary sensorimotor cortex, they are confined to brainstem, cerebellum, and thalamus. During infancy, there occurs a progressive evolution in the pattern of glucose metabolism in the parietal, temporal, striate, dorsolateral occipital, and frontal cortices, in this order. Only by the end of the first year do the glucose metabolic patterns qualitatively resemble those of the normal young adult (Chugani).

Behavior during infancy and early childhood is also the subject of a substantial literature, contributed more by psychologists than neurologists. In particular they have explored sensorimotor performance in the first year and language and social development in early childhood. In the first 6 years of life, the infant and young child traverse far more ground developmentally than they ever will again in a similar period. From the newborn state, when the infant demonstrates a few primitive feeding and postural reflexes, there are acquired, within a few months, smiling and head and hand-eye control; by 6 months, the ability to sit; by 10 months, the strength to stand; by 12 months, the muscle coordination required to walk; by 2 years, the ability to run; and by 6 years, mastery of the rudiments of a game of baseball or a musical skill. On the perceptual side, the neonate progresses, in less than 3 months, from a state in which ocular control is tentative and tonic deviation of the eyes occurs only in response to labyrinthine stimulation to one in which he or she is able to fixate and follow an object. (This last corresponds to the development of the macula.) Much later the child is able to make fine discriminations of color, form, and size. Gesell has provided a graphic summation of the variety and developmental sweep of a child’s behavior. He writes:

At birth the child reflexly grasps the examiner’s finger, with eyes crudely wandering or vacantly transfixed . . . and by the sixth year the child adaptively scans the perimeter of a square or triangle, reproducing each form with directed crayon. The birth cry, scant in modulation and social meaning, marks the low level of language, which in two years passes from babbling to word formation that soon is integrated into sentence structure, and in six years to elaborated syntactic speech with questions and even primitive ideas of causality. In personality makeup . . . the school beginner is already so highly organized, both socially and biologically, that he foreshadows the sort of individual he will be in later years.

The studies of Gesell and Amatruda and of others represent attempts to establish age-linked standards of behavioral development, but the difficulties of using such rating scales are considerable. The components of behavior that have been chosen as a frame of reference are not likely to be of uniform physiologic value or of comparable complexity, and they have seldom been standardized on large populations drawn from different cultures. Also, the ex-
aminations at specified ages are cross-sectional assessments, which give little idea of the dynamics of behavioral development. As already stated, temporal patterns of behavior reveal an extraordinary degree of variation in their emergence, increment, and decrement as well as marked variation from one individual to another.

The predictive value of developmental assessment has been the subject of a lively dispute. Gesell took the position that careful observation of a large number of infants, with accurate recording of the age at which various skills are acquired, permits the establishment of norms or averages. From such a framework one can determine the level of developmental attainment, expressed as the development quotient (DQ = developmental age/chronological age), and thus ascertain whether any given child is superior, average, or inferior. After examining 10,000 infants over a period of 40 years, Gesell concluded that “attained growth is an indicator of past growth processes and a foreteller of growth yet to be achieved.” In other words, the DQ predicts potential attainment.

The other position—taken by Anderson and others—is that developmental attainments are of no real value in predicting the level of intelligence but are measures of completely different functions. Illingworth and most clinicians, including the authors, have taken an intermediate position, that the developmental scale in early life is a useful source of information, but it must always be combined with a full clinical assessment. When this is done, the clinician has a reasonably certain means of detecting mental retardation and other forms of neurologic impairment.

The trajectory of rapid growth and maturation continues in late childhood and adolescence, though at a slower pace than before. Motor skills attain their maximal precision in the performances of athletes, artists, and musicians, whose peak development is at maturity (age 18 to 21). Intelligence and the capacity for reflective thought and the manipulation of mathematical symbols become possible only in adolescence and later. Emotional control, precocious in the school age and all through adolescence, stabilizes in adulthood. We tend to think of all these phenomena as being achieved through the stresses of human relations, which are conditioned and habituated by the powerful influences of social approval. In this extensive and pervasive interaction between the individual and the environment, which is the preoccupation of the child psychiatrist, it is well to remember that the processes of extrinsic and intrinsic organization can be separated only for the purpose of analytic discussion. There is always interdependence rather than conflict between them.

**Motor Development**

As indicated above (and in Table 28-4), the wide variety and seemingly random movements displayed by the healthy neonate are from birth, and certainly within days, firmly organized into reflexive-instinctual patterns called *automatisms*. The most testable of the automatisms are blinking in response to light, tonic deviation of the eyes in response to labyrinthine stimulation (turning of the head), prehensile and sucking movements of the lips in response to labial contact, swallowing, avoidance movements of the head and neck, startle reaction (Moro response) in response to loud noise or dropping of the head into an extended position, grasp reflexes, and support, stepping, and placing movements. This repertoire of movements, as mentioned earlier, depends on reflexes organized at the spinal and brainstem levels. Only the placing reactions, ocular fixation, and following movements (the latter are established by the third month) are thought to depend on emerging cortical connections, but even this is debatable. In the neonatal period, when little of the cerebrum has begun to function, extensive cerebral lesions may cause no derangement of motor function and may pass unnoticed unless special methods of examination—sensory evoked potentials, EEG, computed tomography (CT), and MRI—are used. Of clinically testable neurologic phenomena in the neonatal period, disturbances of ocular movement, seizures, tremulousness of the arms, impaired arousal reactions and muscular tone—all of which relate essentially to upper brainstem and diencephalic mechanisms—provide the most reliable clues to the presence of neurologic disease. Prechtl and associates have documented the importance of disturbances of these neurologic functions at this early age as predictors of retarded development.

During early infancy, the motor system undergoes a variety of differentiations as visual-, auditory-, and tactile-motor mechanisms develop. Bodily postures are modified to accommodate these complex sensorimotor acquisitions. In the normal infant, these emerging motor differentiations and elaborations follow a time schedule prescribed by the maturation of neural connections. Normalcy is expressed by the age at which each of these appear, as shown in Table 28-4. It is also evident from this table that reflex and instinctual motor activities are the most important means of evaluating early development. Moreover, in the normally developing infant, some of these activities disappear as others appear. For example, the grasp reflex, extinction of the limbs without a flexor phase, Moro response, tonic neck reflexes, and crossed adduction in response to eliciting the knee jerk gradually become less prominent and are usually not elicitable by the sixth month. The absence of these reflexes in the first few months of life and their persistence beyond this time indicate a defect in cerebral development, as described further on, under “Delays in Motor Development.” By contrast, neck-righting reflexes, support reactions, the Landau reaction (extending neck and legs when held prone), the parachute maneuver (page 505), and the pincer grasp, which are absent in the first 6 months, begin to appear by the seventh to eighth months and are present in all normal infants by the twelfth month.

Since many functions that are classified as mental at a later period of life have a different anatomic basis than motor functions, it is not surprising that early motor achievements do not correlate closely with childhood intelligence. The converse does not apply, however; delay in the acquisition of motor milestones often correlates with mental retardation. In other words *most mentally retarded children sit, stand, walk, and run at a later age than normal children*, and deviations from this rule are exceptional.

In the period of early childhood, the reflexive-instinctual activities are no longer of help in evaluating cerebral development, and one must turn to the examination of language functions and learned sensory and motor skills. These are outlined in Tables 28-5 and 28-6.

Quite apart from the early stage of motor development, one observes in later childhood and adolescence a remarkable variation in levels of muscular activity, strength, and coordination. Motor acquisitions of later childhood—such as hopping on one foot, kicking a ball, jumping over a line, walking gracefully, dancing, certain skills in sports—are linked to age. Ozeretzkii has combined these in a scale that often discloses arrests in motor development in the mentally retarded. Also in later childhood, precocity in learning complex motor skills as well as skill in games and the development of an all-around interest in athletic activity become evident. By adolescence, high individual physical achievement is well recognized. At the other end of the spectrum are instances of motor

underachievement, ineptitude, and intrinsic awkwardness; a member of this group will easily stand out and be designated as “an awkward child.” Such awkwardness is to be clearly distinguished from the motor impairment associated with a number of cerebral diseases.

Sensory Development

Under normal circumstances, sensory development keeps pace with motor development, and at every age sensorimotor interactions are apparent. However, under conditions of disease, this generalization may not hold; i.e., motor development may remain relatively normal in the face of a sensory defect, or vice versa. The sense organs are fully formed at birth. The neonate is crudely aware of visual, auditory, tactile, and olfactory stimuli, which elicit only low-level reflex responses. Moreover, any stimulus-related response is only to the immediate situation; there is no evidence that previous experience with the stimulus has influenced the response; i.e., that the newborn can learn and remember. The capacity to attend to a stimulus, to fixate on it for any period of time, also comes later. Indeed, the length of fixation time is a quantifiable index of perceptual development in infancy.

Information is available about the time at which the infant makes the first interpretable responses to each of the different modes of stimulation. The most nearly perfect senses in the newborn are those of touch and pain. A series of pinpricks causes distress, whereas an abrasion of the skin seems not to do so. The sense of touch clearly plays a role in feeding behavior. Newborn infants react vigorously to irritating odors such as ammonia and acetic acid, but discrimination between olfactory stimuli is not evident until much later. Sugar solutions initiate and maintain sucking from birth on, whereas quinine (bitter) solutions seldom do, and the latter stimulus elicits avoidance behavior. Hearing in the newborn is manifest within the first few postnatal days. Sharp, quick sounds elicit responsive blinking and sometimes startle. In some infants, the human voice appears to cause similar reactions by the second week. Strong light and objects held before the face evoke reactions in the neonate; later, visual searching is an integrating factor in most projected motor activities.

Sensation in the newborn infant must be judged largely by motor reactions, so that sensory and motor developments seem to run in parallel; but there are discernible maturational stages that constitute sensory milestones, so to speak. This is most apparent in the visual system, which is more easily studied than the other senses. Sustained ocular fixation on an object is observable at term and even in preterm infants; at these ages it is essentially a reflexive phototropic reaction. However, it has been observed that the neonate will consistently gaze at some stimuli more often than others, suggesting that there must already be some elements of perception and differentiation (Fantz). This type of selective attention to stimuli is spoken of as differential fixation. So-called voluntary fixation (i.e., following a moving object) is a later development. Horizontal following occurs at about 50 days; vertical following, at 55 days; and following an object that is moving in a circle, at 2.5 months. Preference for a colored stimulus over a gray one was recorded by Staples by the end of the third month. By 6 months the infant discriminates between colors, and saturated colors can be matched at 30 months. Perception of form, judged by the length of time
spent in looking at different visual presentations, is evident at 2 or 3 months of age (Fantz). At this time infants are attracted more to certain patterns than to colors. At 3 months, most infants have discovered their hands and spend considerable time watching their movements. The ages at which infants begin to observe color, size, shape, and numbers can be determined by means of the Terman-Merrill and Stutzer intelligence tests (see Gibson and Ohlm). Perception of size becomes increasingly accurate in the preschool years. An 18-month-old child discriminates among pictures of familiar animals and recognizes them equally well if they are upside down.

**Visual discrimination** is reflected in manual reactions, just as auditory discrimination is reflected in vocal responses. Much of early visual development (first year) involves perceiving at objects, judging their position, reaching for them, and seizing and manipulating them. The inseparability of sensory and motor functions is never more obvious. Sensory deprivation impedes not only the natural sequences of perceptual awareness of the child’s surroundings but also the development of all motor activities. **Auditory discrimination**—reflected in vocalizations such as babbling and, later, in word formation—is discussed further on in connection with language development.

### The Development of Intelligence

(See also Chap. 21)

The subject of intellectual endowment and the development and testing of intelligence have already been touched upon in Chap. 21. There, it was pointed out that although intelligence is modifiable by training, practice, and schooling, it is much more a matter of native endowment. Intelligent parents tend to beget intelligent children, and unintelligent parents, unintelligent children; this seems to be not simply a question of environment and providing the stimulus to learn. It is evident early in life that some individuals have a superior intelligence; they clearly maintain this superiority all through life, and the opposite pertains in others.

Much of the uncertainty about the relative influence of heredity and environment relates to our imprecise views of what constitutes intelligence. We view intelligence as a general mental capability, embracing a number of primary abilities: the capacity to comprehend complex ideas, learn from experience, think abstractly, reason, plan, draw analogies, and solve problems. Thus intelligence includes a multiplicity of abilities, which probably accounts for a lack of consensus about its mechanism(s). Kurt Goldstein argued that intelligence is a unitary mental capacity, impairment of which gives rise to a fundamental disorder (Grundstö- rung)—a loss of “abstract attitude.” By this he meant an incapacity to deal with objects at a conceptual level and an undue tendency to respond to their immediate, concrete attributes. Everyday experience, however, teaches us that it is not always abstract tasks that suffer most when intelligence is impaired. Indeed, as Zangwill has pointed out, even abstraction may not be a unitary function. Other theoreticians, like Carl Spearman, believed that intelligence comprises a general (g), or core, factor and a series of special (s) factors. In contrast, Thurstone conceived of intelligence as a mosaic of special factors such as drive and curiosity, verbal and arithmetic ability, memory, capacity for abstract thinking, practical skills in manipulating objects, geographic or spatial sense, and athletic and musical ability—each of which appears to be genetically determined. These and other theories concerning intellectual development in the child, such as those of Eysenck and of Gardner and particularly those of Piaget, have been considered in Chap. 21, which should be read as an extension of this section.

</table>
The origins of the development of intelligence are difficult to discern. Intelligence is readily assessed at 8 to 9 months of life, when the infant begins to crawl and explore. For the first time the infant separates itself from the mother. Now, learning proceeds rapidly, as the mother attaches names to objects and helps the baby manipulate them. Gradually the child acquires verbal facility (learning what words mean), memory, color and spatial perception, a concept of number, and the practical use of tools, each at a particular time according to a schedule set largely by the maturational state of the brain. Nevertheless, in these early achievements individuals differ considerably, reflecting to some extent the influence of their parents and others around them. The young child exhibits elementary modes of thinking but is highly suggestible and often incapable of separating imagination from reality.

Neurologists who need a quick and practical method of ascertaining whether an infant or preschool child is measuring up to normal standards for a particular age will find Table 28-5 useful. The main items are drawn from Gesell and Amatruda and from the Denver Developmental Test. In addition, a variety of intelligence tests have been designed to measure the child’s special abilities and increasing success in learning in accordance with age (these are listed in Table 28-6). Starting at 6 to 7 years, there is a steady improvement in intelligence scores that parallels chronologic age in most infants.

* For descriptions of individual tests, see Kinsbourne, 1995.

The most persuasive argument for these tests as an index of native abilities is that individuals drawn from a fairly homogeneous environment tend to maintain the same rating on the intelligence scale throughout their lives. Native endowment appears to set the limits of learning and achievement; opportunity, personality traits, and other factors determine how nearly the individual’s full potential is realized.

The Development of Language

Closely tied to the development of intelligence is the acquisition of language. Indeed, facility with language is one of the best indices of intelligence (Lenneberg). The acquisition of speech and language by the infant and child has been observed methodically by a number of eminent investigators, and their findings provide a background for the understanding of a number of derangements in the development of these functions (Ingram; Rutter and Martin; Minifie and Lloyd).

First, there are the babbling, cooing, and lalling stages, during which the infant, a few weeks old, emits a variety of cooing and then, at about 6 months, babbling sounds in the form of vowel-consonant (labial and nasoguttural) combinations. Later, babbling becomes interspersed with pauses, inflections, and intonations drawn from what the infant hears. At first this appears to be a purely self-initiated activity, being the same in normal and deaf infants. However, study of the latter shows that auditory modifications begin within a period of 2 to 3 months; without an auditory sense, babbler do not produce the variety of random sounds of the normal infant, nor do they begin to imitate the sounds made by the mother. Thus motor speech is stimulated and reinforced mainly by auditory sensations, which become linked to the kinesthetic ones arising from the speech musculature. It is not clear whether the capacity to hear and understand the spoken word precedes or follows the first motor speech. Perhaps it varies from one infant to another, but the dependence of motor speech development on hearing is undeniable. Comprehension seems to postdate the first verbal utterance in most infants.

Soon babbling merges with echo speech, in which short sounds are repeated parrot-like; gradually longer syllable groups are repeated correctly as the praxic function of the speech apparatus develops. As a general rule, the first recognizable words appear by the end of 12 months. Initially these are attached directly to persons and objects and then are used increasingly to designate objects. The word then becomes the symbol, and this substitution greatly facilitates speaking and later thinking about people and objects. Nouns are learned first, then verbs and other parts of speech. Exposure to and correction by parents and siblings gradually shapes vocal behavior, including the development of a distinctive accent, to conform with that of the social group in which the child is raised.

During the second year of life, the child begins to use word combinations. They form the propositions which, according to Hughlings Jackson, are the essence of language. On average, at 18 months the child can combine an average of 1 ½ words; at 2 years,
2 words; at 2 $\frac{1}{2}$ years, 3 words, and at 3 years, 4 words. Pronunciation of words undergoes a similar progression; 90 percent of children can articulate all vowel sounds by the age of 3 years. At a slightly later age the consonants $p$, $b$, $m$, $h$, $w$, $d$, $n$, $t$, and $k$ are enunciated; $ng$ by the age of 4 years; $y$, $j$, $zh$, and $wh$ by 5 to 6 years; and $f$, $l$, $v$, $sh$, $ch$, $s$, $v$, and $th$ by 7 years. Girls tend to acquire articulatory facility somewhat earlier than boys. The vocabulary increases, so that at 18 months the child knows 6 to 20 words; by 24 months, 50 to 200 words; by 3 years, 200 to 400 words. By 4 years, the child is normally capable of telling stories, but with little distinction between fact and fancy. By 6 years, the average child knows several thousand words. Also by that age, children can indicate spatial and temporal relationships and start to inquire about causality. The understanding of spoken language always exceeds the child’s speaking vocabulary; that is to say, most children understand more than they can say.

The next stage of language development is reading. Here there must be an association of graphic symbols with the auditory, visual, and kinesthetic images of words already acquired. Usually the written word is learned by associating it with the spoken word rather than with the seen object. The integrity of the superior gyrus of the temporal lobe (Wernicke’s area) and contiguous parieto-occipital areas of the dominant hemisphere are essential to the establishment of these cross-modal associations. Writing is learned soon after reading, the audiovisual symbols of words being linked to cursive movements of the hand. The tradition of beginning grade school at 6 years is based not on an arbitrary decision but on the empirically determined age at which the nervous system of the average child is ready to learn and execute the tasks of reading, writing, and—soon thereafter—calculating.

Once language is fully acquired, it is integrated into all aspects of complex action and behavior. Movements of volitional type are activated by a spoken command or the individual’s inner phrasing of an intended action. Every plan for the solution of a problem must be cast into language, and the final result is analyzed in verbal terms. Thinking and language are therefore inseparable.

Anthropologists see in all this a grander scheme wherein the individual recapitulates the language development of the human race. They point out that in primitive peoples, language consisted of gestures and the utterance of simple sounds expressing emotion and that, over periods of time, movements and sounds became the conventional signs and verbal symbols of objects. Later these sounds came to designate the abstract qualities of objects. Historically, signs and spoken language were the first means of human communication; graphic records appeared much later. Native Americans, for instance, never reached the level of syllabic written language. Writing commenced as pictorial representation and only much later were alphabets devised. The reading and writing of words are comparatively late achievements.

For further details concerning communicative and cognitive abilities and methods of assessment, the reader should consult the monograph by Minifie and Lloyd.

**Sexual Development**

The terms sexual and sexuality have several meanings in medical and nonmedical writings. The most obvious one relates to the functions of the male and female sexual organs through which procreation occurs and the survival of the species is assured as well as to behaviors that serve to attract the opposite sex and ultimately lead to mating. The terms refer also to a person’s concern or preoccupation with sex or his erotic desires or activities. A more ambiguous meaning has been proposed by some psychologists, for whom the term is equated with all growth and development, the experience of pleasure, and survival.

Much of Freudian psychoanalytic theory centers on the sexual development of the child and—on the basis of questionable observations—espouses the view that repression of the sexual impulse and the psychic conflicts resulting therefrom are the main sources of neurosis and possibly psychosis.

The following are the main chronological steps in sexual development, taken from the observations of Gesell and colleagues and itemized in de Ajuriaguerra’s monograph:

- 18 months Infant applies term baby to both boys and girls.
- 30 months Sexual organs noticed and touched when naked.
- Boy knows his penis is same as father’s. Uses terms boy and girl.
- 3 years Gives verbal expression to differences between sexes and their different postures in urination. Likes to touch adults, especially mother’s breasts.
- 4 years Some pleasure in exhibitionism.
- 5 years Conscious of sexual organs of others. Asks why father does not have breasts or sister a penis.
- 6 years Boys and girls interested in mutual examination of sexual organs. Ask how babies come out of mother and where they came from.
- 7 years First hint of attraction to opposite sex.
- 8 years Teases and jokes about sexual matters.
- 9 years Interested in details of sexual organs. Becomes shy in appearing nude before father and mother. In groups, each sex prefers to be separate.
- Prepubertal In this period, attachments formed with older person of same sex (girlhood crushes); in boys, attachments to members of same sex (gang formation). One observes here homosexual tendencies.
- Puberty Sexes clearly separated. In girls, menstruation and their different postures in urination. Likes to touch adults, especially mother’s breasts.

Penile erections occur intermittently in both infantile and childhood periods. In later childhood, erection is self-initiated and still later is carried to the point of ejaculation and orgasm (masturbation). The timetable of the menarche and other aspects of sexual development is not uniform; and there is considerable variation. If sexuality is not allowed natural expression, it often becomes a source of worry and preoccupation. Some 10 percent of the population fails to develop heterosexual orientation.

Derangements of psychosexual function are discussed on page 449.

**Homosexuality** The homosexual is motivated in adult life by a preferential erotic attraction to members of the same sex. Most psychiatrists exclude from the definition of homosexuality those patterns of behavior that are not motivated by specific preferential desire, such as the incidental homosexuality of adolescents and the situational homosexuality of prisoners.

Figures on incidence are difficult to secure. According to the early reports of Kinsey and colleagues, approximately 4 percent of
American males are exclusively homosexual and 8 percent have been “more or less exclusively homosexual for at least three years, sometime between the ages of 16 and 65.” For females, the incidence is lower, perhaps half that for males. It was estimated, on the basis of the examination of large numbers of military personnel during World War II, that 1 to 2 percent of servicemen were exclusively or predominantly homosexual. More recent estimates, both in men and women, range from 1 to 5 percent (see LeVay and Hamer). These widely variable figures share a problem with all estimates derived from surveys and questionnaires: they cannot count people who do not wish to be counted.

The origins of homosexuality are obscure. We favor the hypothesis that differences or variations in genetic patterning of the immature nervous system (probably of the hypothalamus) set the sexual predilection during early life. Several morphologic studies of the hypothalamus are significant in this regard. Swaab and Hofman have reported that the preoptic zone is three times larger in heterosexual males than it is in females, but it is about the same size in homosexual males as it is in females. As mentioned in Chap. 27, LeVay found that an aggregate of neurons in the suprachiasmatic nucleus of the hypothalamus is two to three times larger in heterosexual men than it is in women, and also two and three times larger in heterosexual than in homosexual men. If confirmed, these findings, which have been disputed by Byrne, would support the view that homosexuality has a biologic basis. Genetic studies point in the same direction. Pooled data from five studies in men have shown that about 57 percent of identical twins (and 13 percent of brothers) of homosexual men are also homosexual. The figures for lesbians are much the same. The inheritance pattern of male homosexuality comes from the maternal side, implicating a gene on the X chromosome (LeVay and Hamer).

Psychoanalytic explanations of homosexuality have never been substantiated. Attempts to demonstrate an endocrine basis for homosexuality have also failed. The most widely held current view is that homosexuality is not a mental or a personality disorder, though it may at times lead to secondary reactive neurotic disturbances. The studies of Kinsey and colleagues indicate that a homosexual orientation cannot be traced to a single social or psychologic root. Instead, as indicated above, homosexuality seems to arise from a deep-seated predisposition, probably biologic in origin and as ingrained as heterosexuality. The status of bisexuality is undetermined.

### The Development of Personality and Social Adaptation

(See also Chap. 56)

**Personality**, the most inclusive of all psychologic terms, encompasses all the physical and psychologic traits that distinguish one individual from every other. The notion that one’s physical characteristics are determined by inheritance is a fundamental tenet of biology. One has but to observe the resemblances between parent and child to confirm this view. Just as no two persons are physically identical, not even monozygotic twins, so too do they differ in any other refined quality one chooses to measure. These differences, together with certain predilections to disease, explain why any one person may have an unpredictable reaction to a pathogenic agent. Strictly speaking, the normal person is an abstraction, just as is a typical example of any disease. However, it is in other, seemingly nonphysical attributes that individuals display the greatest differences. Here reference is made to their variable place on a scale of energy, capacity for effective work, sensitivity, temperament, emotional responsivity, aggressivity or passivity, risk-taking, ethical sense, flexibility, and tolerance to change and stress. The composite of these qualities constitutes the human personality or character.

In the formation of personality, especially the part concerned with feeling and emotional sensitivity, basic temperament surely plays a large part. By nature, some children from the beginning seem to be happy, cheerful, and unconcerned about immediate frustrations; others are the opposite. By the third month of life, Birch and Belmont recognized individual differences in activity-passivity, regularity-irregularity, intensity of action, approach-withdrawal, adaptivity-unadaptivity, high-low threshold of response to stimulation, positive-negative mood, high-low selectivity, and high-low distractibility. Ratings at this early age were found to correlate with the results of examinations made at 5 years. Kagan and Moss recognized the trait of timidity as early as 6 months of age and noted that it persists lifelong.

The more common aspects of personality—i.e., anxiety or serenity, timidity or boldness, the power of instinctual drives and need of satisfaction, sympathy for others, sensitivity to criticism, and degree of disorganization resulting from adverse circumstances—are presumed to be genetically determined. Identical twins raised apart are remarkably alike in these and many other personality traits (and have the same IQs, within a few points) (Moser et al). The strong genetic influence on personality development has also been demonstrated by Scarr and associates. The related subject of the development of a moral sense that can be said to be part of an individual’s personality has been subject to several competing theories. The interested reader is referred to Damon’s summary of the topic.

Disorders of personality and the genetic predisposition to certain personality traits are discussed further in Chap 56.

**Social behavior**, like other neurologic and psychologic functions in general, depends to a great extent on the development and maturation of the brain. Involved also are genetic and environmental factors, for one cannot adapt to society except in the presence of other people; i.e., social interaction is necessary for the emergence of many basic biologic traits. The roots of social behavior are traceable to certain instinctive patterns that are progressively elaborated by conditioned emotional reactions. In the long series of human interactions—first with parents, then with siblings and other children, and finally with a widening circle of individuals in the classroom and community—the capacity to cooperate, to subjugate one’s own egocentric needs to those of the group, and to lead or be led appear as secondary modes of response (i.e., secondary to some of the basic impulses of anger, fear, self-protection, love, and pleasure). The sources of these social reactions are even more obscure than those of temperament, character, and intelligence.

In children, difficulty in social adaptation tends first to be manifest by an inability to take their places in a classroom. However, the greatest demands and frustrations in social development are likely to occur in late childhood and adolescence. The development of adult gonadal function and the further evolution of psychosexual impulses create a bewildering array of new challenges in social adaptation. These types of social adjustment continue as long as life continues. As social roles change, as intellectual and physical capacities first advance and later recede, new challenges demand new adaptations.
Delays in Motor Development

A delay in motor development is often accompanied by mental retardation, in which case both are parts of a developmental lag or immaturity of the entire cerebrum. The most severe forms of delayed motor development, associated with spasticity and athetosis, are usually manifestations of particular prenatal and paranatal diseases of the brain; these are discussed in Chap. 38.

In assessing developmental abnormalities of the motor system in the neonate and young infant, the following maneuvers, which elicit certain postures and reflexive movements, are particularly useful:

1. The Moro response is the infant’s reaction to startle and can be evoked by suddenly withdrawing support of the head and allowing the neck to extend. A loud noise, slapping the bed, or jerking one leg will have the same effect—causing an elevation and abduction of the arms followed by a clasping movement to the midline. This response is present in all newborns and infants up to 4 or 5 months of age, and its absence indicates a profound disorder of the motor system. An absent or inadequate Moro response on one side is found in infants with hemiplegia, brachial plexus palsy, or a fractured clavicle. Persistence of the Moro response beyond 4 or 5 months of age is noted only in infants with severe neurologic defects.

2. The tonic neck reflex consisting of extension of the arm and leg on the side to which the head is passively turned and flexion of the opposite limbs, if obligatory and sustained, is a sign at any age of pyramidal or extrapyramidal motor abnormality. Barlow reports that he has obtained this reflex in 25 percent of mentally retarded infants at 9 to 10 months of age. Fragments of the reflex, such as a brief extension of one arm, may be elicited in 60 percent of normal infants at 1 to 2 months of age and may be adopted spontaneously by the infant up to 6 months of age. As with the Moro response, persistence beyond this age represents a malfunction of the nervous system.

3. The placing reaction in which the foot or hand, brought into contact with the edge of a table, is lifted automatically and placed on the flat surface, is present in all normal newborns. Its absence or asymmetry under 6 months of age indicates a motor abnormality.

4. In the Landau maneuver, the infant, if suspended horizontally in the prone position, will extend the neck and trunk and will break the trunk extension when the neck is passively flexed. This reaction is present by 6 months; its delayed appearance in a hypotonic child is indicative of a faulty motor apparatus.

5. If an infant is held prone in the horizontal position and is then dropped toward the bed, an extension of the arms is evoked, as if to break the fall. This is known as the parachute response and is elicitable in most 9-month-old infants. If it is asymmetrical, it indicates a unilateral motor abnormality.

The detection of gross delays or abnormalities of motor development in the neonatal or early infantile period of life is aided by tests of tendon and plantar reflexes. Arm reflexes are always rather difficult to obtain in infants, and a normal neonate may have a few beats of ankle clonus. The plantar response tends to be wavering and uncertain in pattern. However, a consistent extension of the great toe and fanning of the toes on stroking the side of the foot is abnormal at any age.

The early detection of “cerebral palsy” is hampered by the fact that the corticospinal tract is not fully myelinated until 18 months of age, allowing only quasivoluntary movements up to this time. For this reason, a congenital hemiparesis may not be evident until many months after birth. Even then it is manifest only by subtle signs, such as holding the hand in a fist or posture or clumsiness in reaching for objects and in transferring them from one hand to the other. Later, the leg is seen to be less active as the infant crawls, steps, and places the foot. Early hand dominance should always raise the suspicion of a motor defect on the opposite side. In the upper limb, the characteristic catch and yielding resistance of spasticity is most evident in passive abduction of the arm, extension of the elbow, dorsiflexion of the wrist, and supination of the forearm; in the leg, the change in tone is best detected by passive flexion of the knee. However, the time of appearance and degree of spasticity are variable from child to child. The stretch reflexes are hyperactive, and the plantar reflex may be extensor on the affected side. With bilateral hemiplegia, the same abnormalities are detectable, but there is a greater likelihood of pseudobulbar manifestations, with delayed, poorly enunciated speech. Later, intelligence is likely to be impaired (in 40 percent of hemiplegics and 70 percent of quadriplegics). In diparesis or diplegia, hypotonia gives way to spasticity and the same delay in motor development except that it predominates in the legs. Aside from the hereditary spastic paraplegias, which may become evident in the second and third years, the common causes of weak spastic legs are prematurity and matrix hemorrhages. These various forms of cerebral palsy are described in Chap. 38.

Developmental motor delay and other abnormalities are present in a large proportion of infants with hypotonia. When the “floppy” infant is lifted and its limbs are passively manipulated, there is little muscle reactivity. In the supine position, the weakness and laxity result in a “frog-leg” posture, along with an increased mobility at the ankles and hips. Hypotonia, if generalized and accompanied by an absence of tendon reflexes, is most often due to Werdnig-Hoffmann disease (an early-life loss of anterior horn cells-spinal muscular atrophy), although the range of possible diagnoses is large and includes diseases of muscle, nerve, and the central nervous system (see Chaps. 38 and 52). The other causes of this type of neonatal and infantile hypotonia—muscular dystrophies and congenital myopathies, maternal myasthenia gravis, polynuropathies, Down syndrome, Prader-Willi syndrome, and spinal cord injuries—are described in their appropriate chapters. Hypotonia that arises in utero may be accompanied by congenital fixed contractures of the joints, termed arthrogryposis, as discussed in Chap. 52.

Infants who will later manifest a central motor defect can sometimes be recognized by the briskness of their tendon reflexes and by the postures they assume when lifted. In the normal infant, the legs are flexed, slightly rotated externally, and associated with vigorous kicking movements. The hypotonic infant with a defect of the motor projection pathways may extend the legs or rotate them internally, with dorsiflexion of the feet and toes.
ally, the legs are firmly flexed, but in either instance relatively few movements are made.

When hypotonia is a forerunner of an extrapyramidal motor disorder (e.g., so-called double athetosis, another type of cerebral palsy), the first hint of abnormality may be an opisthotonic posturing of the head and neck. However, involuntary choreic movements usually do not appear in the upper limbs before 5 to 6 months of age and often are so slight as to be overlooked. They worsen as the infant matures and by 12 months assume a more athetotic character, often combined with tremor. Tone in the affected limbs is by then increased but may be interrupted during passive manipulation.

When hypotonia is a prelude to a cerebellar motor defect, the ataxia becomes apparent when the infant makes the first reaching movements. Tremulous, irregular movements of the trunk and head are seen when the infant attempts to sit without support. Still later, as the infant attempts to stand, there is unsteadiness of the entire body.

In distinction to the gross deficits in motor development described above, there is a relatively small but distinct group of young children who exhibit only mild abnormalities of muscle tone, clumsiness, or unusual postures or rhythmic movements of the hands, tremor, and ataxia (“fine motor deficit”). Such awkwardness in the somewhat older child are referred to as “soft signs” and have been extensively described by Gubbay and colleagues in what they called “the clumsy child.” Like speech delay and dyslexia, fine motor deficits of this sort are more frequent in males. Tirosh found that intranatal problems were more prevalent among children with fine motor deficits (compared to those with gross motor deficits), as were minor physical anomalies and seizures.

Systemic diseases in infancy pose special problems in evaluation of the motor system. The achievement of motor milestones is delayed by illnesses such as congenital heart disease (especially cyanotic forms), cystic fibrosis, renal and hepatic diseases, infections, and surgical procedures. Under such conditions one does well to deal with the immediate illnesses and defer pronouncements about the status of cerebral function. The brain proves to be simultaneously affected in 25 percent of patients with serious forms of congenital heart disease and an even higher proportion of patients with rubella and Coxsackie B viral infections. In a disease such as cystic fibrosis, where the brain is not affected, it is advisable to depend more on the analysis of language development than on assessment of motor function, because muscular activity may be generally enfeebled.

**Delays in Sensory Development**

Failure to see and to hear are the most important sensory defects affecting the infant and child. When both senses are affected, a severe cerebral deficit is usually responsible; only at a later age, when the child is more stable, does it become apparent that the trouble is not with the peripheral sensory apparatus but with the central integrating mechanisms of the brain.

Failure of development of visual function is usually revealed by a disorder of ocular movements. Any defect of the refractive apparatus or the acuity of the central visual pathways results in wandering, jerky movements of the eyes. The optic discs may be atrophic in such cases, but it should be pointed out that the discs in infants tend naturally to be paler than those of an older child. In congenital hypoplasia of the optic nerves, the nerve heads are extremely small. Defects in the retina and choroid are detectable by funduscopy. Faulty vision becomes increasingly apparent in older infants when the normal sequences of hand inspection and visuomotor coordination fail to emerge. Retention of pupillary light reflexes in a sightless child signifies a defect in the geniculocarotic tracts or occipital lobes—conditions that may be confirmed by MRI and testing of visual evoked responses.

With respect to hearing, again there is the difficulty in evaluating this function in an infant. Normally, after a few weeks of life, alert parents notice a brisk startle to loud noises and a response to other sounds. A tinkling bell brought from behind the infant usually results in hearkening or head turning and visual searching, but a lack of these responses warns only of the most severe hearing defects. The detection of slight degrees of deafness, enough to interfere with auditory learning, requires special testing. To make the problem even more difficult, both a peripheral and a central disorder may be present in some conditions, such as keratitis. Brainstem auditory-evoked responses (BAERs) are particularly helpful in confirming peripheral (cochlear and eighth nerve) abnormalities in the infant and young child. After the first few months, impaired hearing becomes more obvious and interferes with language development, as described further on.

**RESTRICTED DEVELOPMENTAL ABNORMALITIES**

A considerable portion of neuropediatric practice is committed to the diagnosis and management of children with learning disabilities. These problems usually come to light in the school-age child (hence the term school dysfunction), whose aptitude for classroom learning is thought to be inferior to his general intelligence. The medical referral may be from a parent, teacher, or psychologist. The clinician’s objective is to determine by history and examination whether there is (1) a general congenital developmental abnormality impairing intelligence; or (2) a specific deficit in reading, writing, arithmetic, or attention, any one of which may interfere with the child’s ability to learn; or (3) neither of these—for example, a behavior disorder or home situation that interferes with schooling; or (4) a primary sensory defect, particularly in audition.

Once diagnosis is achieved, the goal of management, undertaken in collaboration with psychologists and educators, is to fashion a program of remedial exercises that will maximize the child’s skills to a point commensurate with his talent and aptitude, and restore his self-confidence (see Rosenberger).

**Disorders in the Development of Speech and Language**

In the pediatric age period and extending into adult life, one encounters an interesting assortment of developmental disorders of speech and language. Many patients with such disorders come from families in which similar speech defects, ambidexterity, and lefthandedness are also frequent. Males predominate; in some series, male-to-female ratios as high as 10:1 have been reported.

Developmental disorders of speech and language are far more frequent than acquired disorders, i.e., aphasia. The former include developmental speech delay, congenital deafness with speech delay, developmental word deafness, dyslexia (special reading disability), cluttered speech, infantilisms of speech, and stuttering or stammering, and mechanical disorders such as cleft palate speech. Often in these disorders, the various stages of language develop-
ment described earlier are not attained at the usual age and may not be achieved even by adulthood. Disorders of this type, restricted to the language areas of the cerebrum, are far more frequently due to slowness in the normal processes of maturation than to an acquired disease. With the possible exception of developmental dyslexia (see further on), cerebral lesions have not been described in these cases, though it must be emphasized that only a small number of brains of such individuals become available for study and of these only a few have been thoroughly studied by proper methods.

In discussing the developmental disorders of speech and language, we have adopted a conventional classification. Not usually included in such a classification are the many mundane peculiarities of speech and language that are usually accepted without comment—lack of fluency, inability to speak uninterruptedly in complete sentences, and lack of proper intonation, inflection, and melody of speech (dysprosody).

**Developmental Speech Delay**  
Fully two-thirds of children say their first words between 9 and 12 months of age and their first word combinations before their second birthday; when this does not happen, it becomes a matter of parental concern. Children who fail to reach these milestones at the stated times fall into two general categories. In one group there is no clear evidence of mental retardation or impairment of neurologic or auditory function. In a second group, the speech delay has an overt pathologic basis.

The first group, comprising otherwise normal children who talk late, is the more puzzling. It is virtually impossible to predict whether such a child’s speech will eventually be normal in all respects and just when this will occur. Prelanguage speech continues into the period when words and phrases should normally be used in propositional speech. The combinations of sounds are close to the standard of normal vowel-consonant combinations of the 1- to 2-year-old, and they may be strung together as if forming sentences. Yet, as time passes, the child may utter only a few understandable words, even by the third or fourth year. Three out of four such patients will be boys and often one discovers a family history of delayed speech. When the child finally begins to talk, he may skip the early stages of spoken language and progress rapidly to speak in full sentences and to develop fluent speech and language in weeks or months. During the period of speech delay, the understanding of words and general intelligence develop normally, and communication by gestures may be remarkably facile. In such children, motor speech delay does not presage mental backwardness. (It is said that Albert Einstein did not speak until the age of 4 and lacked fluency at age 9.)

Nevertheless, the eventual acquisition of fluent speech is no guarantee of normality (Rutter and Martin). Many such children do have later educational difficulties, mainly because of dyslexia and dysgraphia, a combination that is sometimes inherited as an autosomal dominant trait—again, more frequently in boys (see further on). In a smaller subgroup, articulation remains infantile and the content of speech is impoverished semantically and syntactically. Yet others, as they begin to speak, express themselves fluently, but with distortions, omissions, and cluttering of words, but such patients usually recover.

A second broad group of children with speech delay or retarded speech development (no words by 18 months, no phrases by 30 months) comprises those in whom an overt pathologic basis is evident. In clinics where children of the latter type are studied systematically, 35 to 50 percent of cases occur in those with mental retardation or “cerebral palsy.” Hearing deficit explains many of the other cases, as discussed below, and a few represent what appears to be a lack of maturation of the motor speech areas or an acquired lesion in these parts. Only in this small latter group is it appropriate to refer to the language disorder as aphasia—i.e., a derangement or loss of language due to a cerebral lesion. Aphasia, when it occurs as the result of an acquired lesion (vascular, traumatic), is essentially of the motor variety and typically lasts but a few months in the child. It may be accompanied by a right-sided hemiplegia. An interesting type of acquired aphasia, possibly encephalitic, has been described by Landau and Kleffner in association with seizures and bitemporal focal discharges in the EEG (see page 289).

**Congenital Deafness**  
Speech delay due to congenital deafness, whether peripheral (loss of pure-tone acuity) or central (pure-tone threshold normal by audiogram), is a most important condition but may at first be difficult to discern. One suspects that faulty hearing is causal when there is a history of familial deaf mutism, congenital rubella, erythroblastosis fetalis, meningitis, chronic bilateral ear infections, or the administration of ototoxic drugs to the pregnant mother or newborn infant—the well-known antecedents of deafness. It is estimated that approximately 3 million American children have hearing defects; 0.1 percent of the school population are deaf and 1.5 percent are hard of hearing. The parents’ attention may be drawn to a defect in hearing when the infant fails to heed loud noises, to turn the eyes to sound sources outside the immediate visual fields, and to react to music; but in other instances it is the delay in speaking that calls attention to it.

The deaf child makes the transition from crying to cooing and babbling at the usual age of 3 to 5 months. After the sixth month, however, the child becomes much quieter, and the usual repertoire of babbling sounds becomes stereotyped and unchanging, though still uttered with pleasant voice. A more conspicuous failure comes somewhat later, when babbling fails to give way to word formation. Should deafness develop within the first few years of life, the child gradually loses such speech as had been acquired but can be re-taught by the lipreading method. Speech, however, is harsh, poorly modulated, and unpleasant and accompanied by many peculiar squeals and snorting or grunting noises. Social and other acquisitions appear at the expected times in the congenitally deaf child, unlike the mentally retarded child. The deaf child seems eager to communicate and makes known all his needs by gesture or pantomime—often very cleverly. The deaf child may attract attention by vivid facial expressions, motions of the lips, nodding, or head shaking. The Leiter performance scale, which makes no use of sounds, will show that intelligence is normal. Deafness can be demonstrated at an early age by careful observation of the child’s responses to sounds and by free-field audiometry, but the full range of hearing cannot be accurately tested before the age of 3 or 4 years. Recording of auditory-evoked brainstem potentials and testing of the labyrinths, which are frequently unresponsive in deaf mutes, may be helpful. Early diagnosis is important in order to fit the child with a hearing aid, if possible, and to begin appropriate language training.

In contrast to the child in whom deafness is the only abnormality, the mentally retarded child generally talks little but may display a rich personality. Autistic children may also be mute; if they speak, echolalia is prominent and the personal “I” is avoided. Blind children of normal intelligence tend to speak slowly and fail to acquire imitative gestures.
Congenital Word Deafness  This disorder—also called developmental receptive dysphasia, verbal auditory agnosia, or central deafness—is rare and may be difficult to distinguish from peripheral deafness. Usually the parents have noted that the word-deaf child responds to loud noises and music, but obviously this does not assure perfect hearing, particularly for high tones. The word-deaf child does not understand what is said, and delay and distortion of speech are evident.

Presumably, the receptive auditory elements of the dominant temporal cortex fail to discriminate the complex acoustic patterns of words and to associate them with visual images of people and objects. Despite intact pure-tone hearing, the child does not seem to hear word patterns properly and fails to reproduce them in natural speech. In other ways the child may be bright, but more often this auditory imperception of words is associated with hyperactivity, inattentiveness, bizarre behavior, or other perceptual defects incident to focal brain damage, particularly of the temporal lobes. Word-deaf children may chatter incessantly and often adopt a language of their own design, which the parents come to understand. This peculiar type of speech is known as idioglossia. It is also observed in children with marked articulatory defects.

Speech rehabilitation of the bright word-deaf child follows along the same lines as that of the congenitally deaf one. Such a child learns to lip-read quickly and is very facile at acting out his or her own ideas.

Congenital Inarticulation  In this developmental defect the child seems unable to coordinate the vocal, articulatory, and respiratory musculature for the purpose of speaking. Again, boys are affected more often than girls, and there is often a family history of the disorder, although the data are not quite sufficient to establish the pattern of inheritance. The incidence is 1 in every 200 children. The motor, sensory, emotional, and social attainments correspond to the norms for age, although in a few cases, a minority in the authors’ opinion, there has been some indication of cranial nerve abnormality in the first months of life (ptosis, facial asymmetry, strange neonatal cry, and altered phonation).

In children with congenital inarticulation, the prelanguage sounds are probably abnormal, but this aspect of the speech disorder has not been well studied. Babbling tends to be deficient, and, in the second year, in attempting to say something, the child makes noises that do not sound at all like language; in this way the child is unlike the late talker already described. Again, the understanding of language is entirely normal; the comprehension vocabulary is average for age, and the child can appreciate syntax, as indicated by correct responses to questions by nodding or shaking the head and by the execution of complex spoken commands. Usually such patients are shy but otherwise quick in responding, cheerful, and without other behavioral disorders. Most are bright, but a combination of congenital inarticulation and mild mental dullness is not uncommon. If many of the spontaneous utterances are intelligible, speech correction should be attempted (by a trained therapist). However, if the child makes no sounds that resemble words, the therapeutic effort should be directed toward a modified school program, and speech rehabilitation should wait until some words are acquired.

Studies of the cerebra of such patients are not available, and it is doubtful if they would show any abnormality by the usual techniques of neuropathologic examination. Occasionally, suspicion of a lesion is raised by focal changes in the EEG or a slight widening of the temporal horn of the left ventricle. All manner of delayed speech is often attributed to “tongue-tie,” i.e., a short lingual frenulum, but we have never been convinced of this causal relationship. Also, psychologists have attributed speech retardation to overprotectiveness or excessive pressure by the parents but these are almost certainly the result rather than the cause of the delay.

A fuller review of this subject can be found in the text The Child with Delayed Speech, edited by Rutter and Martin.

Stuttering and Stammering  These difficulties occur in an estimated 1 to 2 percent of the school population. Often the conditions disappear in late childhood and adolescence; by adulthood, only about 1 in every 300 individuals suffers from a persistent stammer or stutter. Mild degrees are to some extent cultivated and permit a pause in speech for collecting one’s thoughts, and stammering tends to be imitated in certain social circles, as among educated Englishmen (and some Americans).

Stammering and stuttering are difficult to classify. In some respects they belong to and are customarily included in the developmental language disorders, but they differ in being largely centered in articulation. Essentially they represent a disorder of rhythm—an involuntary, repetitive prolongation of speech—due to an insuspressible spasm of the articulatory muscles. The spasm may be tonic and result in a complete blocking of speech (at one time referred to specifically as stammering) or clonic speech, i.e., a rapid series of spasms interrupting the emission of consonants, usually the first letter or syllable of a word (stuttering). There is no valid reason to distinguish between these two forms of the disorder, since they are intermingled, and the terms stammer and stutter are now used synonymously. Certain sounds, particularly p and b, offer greater difficulty than others; paperboy comes out p-p-paper b-b-boy. The problem is usually not apparent when single words are being spoken and dysfluency tends to be worse at the beginning of a sentence or an idea. The severity of the stutter is increased by excitement and stress, as when speaking before others, and is reduced when the stutterer is relaxed and alone or when singing in a chorus. When severe, the spasms may overflow into other groups of muscles, mainly of the face and neck and even of the arms. The muscles involved in stuttering show no fault in actions other than speaking, and all gnostic and semantic aspects of receptive language are intact.

Males are affected four times as often as females. The time of onset of stuttering is mainly at two periods in life—between 2 and 4 years of age, when speech and language are evolving, and between 6 and 8 years, when these functions extend to reciting and reading aloud in the classroom. However, there may be a later onset. Many afflicted children have an associated difficulty in reading and writing. If stuttering is mild, it tends to develop or to be present only during periods of emotional stress, and in four out of five children it disappears entirely or almost so during adolescence or the early adult years (Andrews and Harris). If severe, it persists throughout life regardless of treatment but tends to improve as the patient grows older.

Theories of causation are legion. Slowness in developing hand and eye preference, ambidexterity, or an enforced change from left to right-hand use have been popular explanations of which Orton and Travis were leading advocates. According to their theory, stuttering results from a lack of the necessary degree of unilateral control in the synchronization of bilaterally innervated speech mechanisms. Fox and colleagues support a theory of failure of left hemisphere dominance. By performing PET studies while a subject was reading, they found that the auditory and motor areas of the
The disappearance of mild stuttering with maturation has been attributed incorrectly to all manner of treatment (hypnosis, progressive relaxation, speaking in rhythms, etc.) and used to bolster particular theories of causation. Since stuttering may reappear at times of emotional strain, a psychogenesis has been proposed, but—as pointed out by Orton and by Baker and colleagues—if there are any psychologic abnormalities in the stutterer, they are secondary rather than primary. We have observed that many stutterers, probably as a result of this impediment to free social interaction, do become increasingly fearful of talking and develop feelings of inferiority. By the time adolescence and adulthood are reached, emotional factors are so prominent that many physicians have mistaken stuttering for neurosis. Usually there is little or no evidence of any personality deviation before the onset of stuttering, and psychotherapy has not in our experience had a significant effect on the underlying defect. A strong family history in many cases and male dominance point to a genetic origin, but the inheritance does not follow a readily discernible pattern.

Stuttering is not associated with any detectable weakness or ataxia of the speech musculature. The muscles of speech go into spasm only when called upon to perform the specific act of speaking. The spasms are not invoked by other actions (which may not be as complex or voluntary as speaking), differing in this way from an apraxia and the intention spasm of athetosis. Also, palilalia is a different condition in which a word or phrase, usually the last one in a sentence, is repeated many times with decreasing volume. Perhaps stuttering represents a special category of extrapyramidal dystonic movement disorder, much like writer’s cramp (page 94).

Rarely, in adults as well as in children, stuttering may be acquired as a result of a lesion in the motor speech areas. A distinction has been drawn between developmental and acquired stuttering. The latter is said to interfere with the enunciation of any syllable of a word (not just the first), to favor involvemnt of grammatical and substantive words, and to be unaccompanied by anxiety and facial grimacing. Such distinctions are probably illusory. The reported lesion sites in acquired stuttering are so variable (right frontal, corpus striatum, left temporal, left parietal) as to be difficult to reconcile with proposed theories of developmental stuttering (Fleet and Heilman).

Another form of acquired stuttering is manifestly an expression of an extrapyramidal disorder. Here there occurs a prolonged repetition of syllables (vowel and consonant), which the patient cannot easily interrupt. The abnormality involves throat-clearing and other vocalizations, similar to what is seen in tic disorders.

**Treatment** The therapy of stuttering is difficult to evaluate and, on the whole, the therapy of speech-fluency disorders has been a frustrating effort. As remarked above, all speech-fluency disturbances are modifiable by environmental circumstances. Thus a certain proportion of stutterers will become more fluent under certain conditions, such as reading aloud; others will stutter more severely at this time. Again, a majority of stutterers will be adversely affected by talking on the telephone; a minority are helped by this device. Some stutterers are more fluent under conditions of mild alcohol intoxication. Nearly every stutterer is fluent while singing. Schemes such as the encouragement of associated muscular movements (“penciling,” etc.) and the adoption of a “theatrical” approach to speaking have been advocated. Common to all such efforts has been the difficulty of achieving carryover into the natural speaking environment. Progressive relaxation, hypnosis, delayed auditory feedback, loud noise that masks speech sounds, and many other ancillary measures may help, but only temporarily. Canevini and colleagues have made the interesting observation that stuttering improved in an epileptic treated with levetiracetam, and Rosenberger has commented on other drug therapies.

**Cluttering, or Cluttered Speech** This is another special developmental disorder. It is characterized by uncontrollable speed of speech, which results in truncated, dysrhythmic, and often incoherent utterances. Omissions of consonants, elisions, improper phrasing, and inadequate intonation occur. It is as though the child were too hurried to take the trouble to pronounce each word carefully and to compose sentences. Cluttering is frequently associated with other motor speech impediments. Speech therapy (elocutionary) and maturation may be attended by a restoration of more normal rhythms.

**Other Articulatory Defects** These are most common in preschool children, having an incidence of up to 15 percent. There are several varieties. One is *lisping*, in which the *s* sound is replaced by *th*, e.g., *thimple* for *simple*. Another common condition, *lallation*, or *dyslalia*, is characterized by multiple substitutions or omissions of consonants. Milder degrees consist of difficulty in pronouncing one or two consonants. For example, the letter *r* may be incorrectly pronounced, so that it sounds like *w* or *y*. *Running a race* becomes *wunning a wace* or *yunning a yace*. In severe forms, speech may be almost unintelligible. The child seems to be unaware that his or her speech differs from that of others and is distressed at not being understood. These and similar abnormalities of speech are often present in otherwise normal children and are referred to as “infantilisms.” Why they persist in some individuals is not understood. More important is the fact that in more than 90 percent of cases, these articulatory abnormalities disappear by the age of 8 years, either spontaneously or in response to speech therapy. The latter is best started if these conditions persist into the fifth year. Presumably the natural cycle of motor speech acquisition has only been delayed, not arrested. Such abnormalities, however, are more frequent among the mentally retarded than in normal children; with mental defect, many consonants are persistently mispronounced.

Another type is a congenital form of spastic bulbar speech described by Worster-Drought in which words are spoken slowly, with stiff labial and lingual movements, hyperactive jaw and facial reflexes, and sometimes mild dysphagia and dysphonia. The limbs may be unaffected, in contrast to those of most children with cerebral palsy.

The speech disorder resulting from *cleft palate* is easily recognized. Many of these patients also have a harelip; the two abnormalities together interfere with sucking and later in life with the enunciation of labial and gutturals consonants. The voice has an
Developmental Dyslexia (Congenital Word Blindness) This condition, first described by Hinshelwood in 1896, becomes manifest in an older child who lacks the aptitude for one or more of the specific skills necessary to derive meaning from the printed word. Also defined as a significant discrepancy between “measured intelligence” and “reading achievement” (Hynd et al), it has been found in 3 to 6 percent of all schoolchildren. There are several excellent writings on the subject, to which the interested reader is referred for a detailed account (Orton; Critchley and Critchley; Rutter and Martin; Kinsbourne; Shaywitz; Rosenberger).

The main problem is an inability to read words and also to spell and to write them, despite the ability to see and recognize letters. There is no loss of the ability to recognize the meaning of objects, pictures, and diagrams. According to Shaywitz, these children lack an awareness that words can be broken down into individual units of sound and that each segment of sound is represented by a letter or letters. This has been summarized as a problem in “phonologic processing,” referring to the smallest unit of spoken language, the phoneme, and the inability of dyslexic individuals to appreciate a correspondence between phonemes and their written representation (graphemes). A defect in the decoding of acoustic signals is one postulated mechanism. In addition to the essential visuoperceptual defect, some individuals also manifest a failure of sequencing ability, lack of phonemic segmentation, and altered cognitive processing of language. De Renzi and Luchelli have also noted a deficit of verbal and visual memory.

Much of what has been learned about dyslexia applies to native speakers of English more so than to those who speak Romance languages. English is more complex phonologically than most other languages—for example, using 1120 graphemes to represent 40 phonemes, in contrast to Italian, which uses 33 graphemes to represent 22 phonemes (see Paulesu). Children with native orthographic languages, such as Chinese and Japanese, apparently have a far lower incidence of dyslexia.

Often, before the child enters school, reading failure can be anticipated by a delay in attending to spoken words, difficulty with rhyming games, and speech characterized by frequent mispronunciations, hesitations, and dysfluency; or there may be a delay in learning to speak or in attaining clear articulation. In the early school years there are difficulties in copying, color naming, and formation of number concepts as well as the persistent reversal of letters. Writing appears to be defective because of faulty perception of form and a kind of constructional and directional apraxia. Not infrequently, there is an associated vagueness about the serial order of letters in the alphabet and months in the year, as well as difficulty with numbers (acalculia) and an inability to spell and to read music.
temporal cortex (Casanova et al). (A similar developmental change has been found in the brains of individuals with Down syndrome and with autism.)

Leonard and colleagues, using MRI, have demonstrated several other gyral anomalies in dyslexic subjects. They found, in the planum temporale and neighboring parietal operculum of both hemispheres, that some gyri were missing and others were duplicated. Also, in some dyslexic individuals, the visual evoked responses to rapid low-contrast stimuli are diminished. The latter abnormality may be related to a deficit of large neurons in the lateral geniculate bodies (see Livingstone et al). Stein et al has found that 20 percent of dyslexic children have unstable ocular fixation and that monocular occlusion improves both binocular control and reading.

Specific spelling difficulty probably represents another developmental language disorder, distinct from dyslexia. Additional physiologic data from functional imaging studies support the existence of an abnormal temporoparietal cortex in dyslexics. These regions—particularly the posterior portion of the superior temporal, angular, and supramarginal gyri—are selectively activated during reading in normal individuals but not in dyslexics, who activate very restricted regions of the cerebral hemisphere, mainly Broca’s area. Dyslexics, in addition, recruit other areas during reading, such as the inferior frontal regions, that are not utilized by normal children. It is noteworthy, therefore, that Simos and coworkers were able to show that these functional patterns (using MRI) dramatically normalized after several weeks of intensive training. If nothing else, these findings validate that the localization of the functional problem is the dominant temporoparietal area and support the notion that developmental dyslexia is susceptible to improvement by proper training.

**Treatment** The steady drilling (many hours per week) of a cooperative and motivated child by a skillful teacher over an extended period slowly overcomes the handicap and enables an otherwise intelligent child to read at grade level and to follow a regular program of education successfully. The Orton phonologic method is one of the most successful (for details, see Rosenberger). Secondary school and college students with reading deficits often resort to tape recorders, tutorial aid, and laptop computers.

**Developmental Dysgraphia** Developmental writing disorders differ from dyslexia in having both linguistic and motor (orthographic) aspects. As indicated earlier, dysgraphias are present in many dyslexic children and may be combined with difficulty in calculation (so-called developmental Gerstmann syndrome). Two forms of dysgraphia have been distinguished. In one there is good handwriting and formation of letters and spacing but many misinterpretations of dictated words (linguistic dysgraphia). In the other, there are reversals of letters and letter order and poor alignment (mechanical dysgraphia).

**Developmental Dyscalculia** This disorder, like dyslexia, usually becomes evident in the first few years of grade school, when the child is challenged by tasks of adding and subtracting and, later, multiplying and dividing. In some instances there is an evident disorder in the spatial arrangements of numbers (supposedly a right hemispherical fault); in others, there is a lexical-graphical abnormality (naming and reading the names of numbers) akin toaphasia.

Probably all that has been said about the principles of treatment of developmental dyslexia applies to the kindred states of acalculia and agraphia. The usual type of conventional classroom work does nothing to increase the child’s proficiency in writing and arithmetic, but special tutoring and drills do aid the student to some extent. All of these impairments are often associated with hyperactivity and attentional defects, as described below (Denckla et al).

**Precocious Reading and Calculating** Precocious reading and calculating abilities have also been identified. A 2- or 3-year-old child may read with the skill of an average adult. Extraordinary facility with numbers (mathematical prodigies) and memorization ability (eidetic imagery) are comparable traits. Here, one observes a remarkable overdevelopment of these single faculties. Occasionally, one of these special abilities will be observed in a child with a mild form of autism (Asperger syndrome, see Chap. 38). Such a child may exhibit great skill in performing a mathematical trick but be unable to solve simple arithmetical problems or to understand the meaning of numbers (a kind of “idiot savant”). In the child with Williams syndrome, language and sometimes musical skills are not so much precocious as relatively normal in comparison to the overall mental deficiency, indicating that not all forms of mental retardation involve language.

**Congenital Amusia** One would expect that developmental deficiencies similar to those found for language would exist for music. This condition, commonly known as tone-deafness, has only recently been studied. According to the careful studies of Ayotte and colleagues, there are deficits not only in pitch variation but also in music memorization, singing, and rhythmicity. They propose that the defect in pitch perception is at the root of the other abnormalities. What is also interesting is that amusia occurs without any difficulty in the processing of speech and language, specifically, prosody and prosodic interpretation are preserved. (See Chap. 22 for a discussion of the acquired forms of musical defects.)

**Hyperactivity-Inattention Disorders** (Attention Deficit—Hyperactivity Disorder, ADHD)

Another large portion of ambulatory pediatric neurology practice consists of children who are referred because of failure in school related to overactivity, impulsivity, and inattentiveness. The question often asked is whether they have an identifiable brain disease. When a large number of such cases is analyzed, fully 80 to 85 percent prove to have no major signs of neurologic disease (Barlow). Perhaps 5 percent are mentally subnormal and another 5 percent show some evidence of minimal brain disorder. Many are clumsy. In the larger group without neurologic signs, the IQ is normal, though there are also a number of borderline cases. Boys are found to be more hyperactive and inattentive than girls, just as they often have more trouble in learning to read and write. Dyslexia is frequently associated, as noted above. Girls with ADHD tend to have more trouble with numbers and arithmetic.

Human infants exhibit astonishing differences in amount of activity almost from the first days of life. Some babies are constantly on the move, wiry, and hard to hold; others are placid and slack as a sack of meal. Irwin, who studied motility in the neonate, found a difference of 290 times between the most and least active in terms of amount of movement per 24 h.

Once walking and running begin, children normally enter a period of extreme activity, more so than at any other period of life. The degree of activity, which again varies widely from one child to another, seems not to be correlated with the age of achieving
motor milestones or with motor skill at a later time. Children with cerebral defects tend to exhibit apathy or hyperactivity more often than children without recognizable defects.

Again, two groups of overactive children can be discerned. In one, infants are constitutionally overactive from birth, sleeping less and feeding poorly; by the age of 2 years, the syndrome is obvious. In the other group, an inability to sit quietly only becomes apparent at the preschool age (4 to 6 years). Seldom do such children remain in one position for more than a few seconds, even when watching television. Attention to any task cannot be sustained, hence the term attention deficit—hyperactivity disorder. As a rule, there is also an abnormal impulsivity and often an intolerance of all measures of restraint. Mild degrees of mental retardation and epilepsy and other disabilities are conjoined in some patients.

Once the child is in school, the attention deficit becomes more troubling. Now these children must sit still, watch and listen to the teacher when she speaks to another child, and not react to distracting stimuli. They cannot stay at their desks, take turns in reciting, be quiet, or control their impulsivity. The teacher finds it difficult to discipline them and often insists that the parents seek medical consultation. A few affected children are so hyperactive that they cannot attend regular school. Their behavior verges on the “organic drivennes” that has been known to occur in children whose brains have been injured by encephalitis. In certain families the disorder is probably inherited (Biederman et al). In about half the patients, the hyperactivity subsides gradually, by puberty or soon thereafter, but in the remainder the symptoms persist in modified form into adulthood (Weiss et al). It has also become clear that a group of children exist who have difficulty sustaining concentration but do not manifest hyperactivity or behaviors that betray the attention deficit. It is presumed that they share a similar core problem with hyperkinetic children, and it has been observed that they may be helped in studying and school performance by the same stimulant drugs that are used for the treatment of more overt ADHD.

For a number of years there was a tendency to consider children with the hyperkinetic syndrome as having minimal brain disease. “Soft neurologic signs” such as right-left confusion, mirror movements, minimal “choreic” instability of the hands, awkwardness, finger agnosia, tremor, and borderline hyperreflexia were said to be more frequent among them. These signs, however, are seen so often in normal children that their attribution to disease is invalid. Schain and others therefore substituted the term minimal brain dysfunction, which is no more accurate and simply restates the problem. Lacking altogether are accurate clinicanoatomic and clinicopathologic correlative data.

Some morphologic and physiologic data are available. In an MRI study of the brains of 10 children with hyperactivity—attention deficit disorder, Hynd and colleagues found the width of the right frontal lobe to be smaller than normal; also fairly consistently, there was smallness of the dorsolateral, cingulate, and striatal regions. Unlike dyslexics, in whom the planum temporale tends to be equal in the two hemispheres, the left planum was larger in the attention deficit cases, just as it is in normals. Also, functional imaging studies have suggested that the inability of these children to block impulsive reactions and the improvement that is seen with methylphenidate are accompanied by changes in the striatum. One would expect the prefrontal cortex to be implicated in such a disinhibitory syndrome but data from brain mapping in children with ADHD have been very complex and difficult to interpret. Another approach to understanding the process has been to study a strain of mice that have been genetically altered to eliminate a dopamine transporter gene. These animals display behavioral symptoms that are said to replicate those of ADHD in children and also to respond to stimulants. These observations implicate an abnormality of dopamine and serotonin; the idea is provocative because several genetic linkage studies have suggested an association between ADHD and a polymorphism of the gene that codes for the same dopamine transporter gene.

Apart from the reports of parents and teachers and observation of the child, one is aided in the diagnosis of the attention deficit disorder (and other learning disabilities) by psychometry. An observant psychologist, in performing intelligence tests, notes distractibility and difficulty in sustaining any activity. Erratic performance that is not due to a defect in comprehension is characteristic.

The treatment of the hyperactive child can proceed intelligently only after medical and psychologic explorations have elucidated the context in which the hyperactivity occurs. If the child is hyperactive and inattentive mainly in school and less so in an unstructured environment, it may be that mental retardation or dyslexia, which prevents scholastic success, is a source of frustration and boredom. The child then turns to other activities that may happen to disturb the classroom. Or the hyperactive child may have failed to acquire self-control because of a disorganized home life, and the overactivity may be but one manifestation of anxiety or intolerance of constraint. Clearly problems such as these require a modification of the educational program.

Treatment For overactive children of normal intelligence who have failed to control their impulses, who at all times have boundless energy, require little sleep, exhibit a wriggling restlessness (the choreiform syndrome of Prechtl and Stemmer), and manifest incessant exploratory activity that repeatedly gets them into mischief, even to their own dismay, medical therapy is in order. Paradoxically, stimulants have a quieting effect on these children, whereas phenobarbital and other sedatives may have the opposite effect. Methylphenidate is the drug most widely used. Children under 30 kg are given 5 mg each morning on school days for 2 weeks, after which the dose can be raised to 5 mg morning and noon. Children weighing less than 30 kg can be given a single 20-mg sustained-release tablet each morning. If methylphenidate proves ineffective after several weeks or cannot be tolerated, dextroamphetamine 2.5 to 5 mg three times daily is a suitable substitute. Pemoline is a weaker but sometimes better-tolerated stimulant than the others. If these agents control the activity and improve school performance (they can be continued for a number of years), there is then no need to alter the child’s school program. If stimulants are ineffective, tricyclic antidepressants, particularly desipramine, should be tried. Classroom behavioral conditioning techniques and psychotherapy may be needed for brief periods. Remedial education is reserved for recalcitrant cases.

Certainly the disease is a lifelong problem for a proportion of children, although it is just as clear that many or most “outgrow” it. Hill and Schoener estimate that there is a 50 percent decline in prevalence with each 5 years of growth. In addition to the child with ADHD who grows to adulthood with persistent problems, there has recently emerged an interest in a group of adults who present for the first time with features that they or their physicians attribute to ADHD. Most often these adults come to realize they have had lifelong problems that are similar to the motor restlessness and wandering attention that led to the diagnosis of ADHD in their own children. The efficacy and safety of stimulant drugs in the adult group is not known with certainty, but this class of medications as well as antidepressants has been tried with some success.
In relation to persistent traits of ADHD, several psychiatrists have pointed out that there may be an increase in drug and alcohol dependence among adolescents with the disorder (Zametkin and Ernst) and a connection in a few cases to tic disorders such as Tourette syndrome (page 95). However, it can be said from our general clinical experience that these problems do not arise in the great majority of such children.

**Enuresis**

Voluntary sphincteric control develops according to a predetermined time scale. Usually normal children stop soiling themselves before they can remain dry, and day control precedes night control. Some children are toilet-trained by their second birthday, but many do not acquire full sphincter control until the fourth year. Continuous dribbling usually indicates spina bifida or another form of dysraphism, but in the boy one must look also for obstruction of the bladder neck and in the girl for an ectopic ureter entering the vagina.

When a child 5 years of age or older wets the bed nearly every night and is dry by day, the child is said to have *nocturnal enuresis*. This condition afflicts approximately 10 percent of children between 4 and 14 years of age, boys more than girls, and continues in many cases to be a problem even into adolescence and adulthood. Although mentally retarded children are notably late in acquiring sphincter control (some never do), the majority of enuretic individuals are normal in other respects.

The cause of this condition is disputed. Often there is a family history of the same complaint. It is our impression that night terrors are frequent in this group. Some psychiatrists have insisted that overzealous parents “pressure” the child until he develops a complex about his bedwetting; this is highly doubtful. Punishment, shaming, rewards, etc., may have this effect, but the underlying condition is believed by most neurologists to be a delay in the maturation of higher control of spinal reflex centers during sleep. These and other abnormalities of bladder function in the enuretic child, as well as treatment, are discussed in the chapter on sleep (page 349).

**Sociopathy and Neurosis**

Extremes of egocentrism—lack of understanding of the feelings, needs, and actions of other members of one’s social group—and an inability to judge one’s own strengths and weaknesses stand as the central issues in the development of certain types of neurosis and of borderline personality disorder. Such difficulties usually become manifest by adolescence. The complete detachment of the child with psychosis, the amorality of the constitutional sociopath, the major disturbances in thinking of the schizophrenic, and the mood swings of the manic-depressive also express themselves in many if not most instances by adolescence and sometimes by late childhood. Here one confronts a key problem in psychiatry—the extent to which neurosis, sociopathy, and psychosis have their roots in genetically determined personality traits or in derangements in the affective and social life of the individual, consequent to a harmful environment. In other words, in what measure are the neuroses and other psychiatric disorders determined by early life experiences and to what extent are they genetically determined?

The answers to these questions cannot be given with finality. Experienced modern clinicians tend to believe that genetic factors are more important than environmental ones. The discovery that unusually tall males with severe acne vulgaris and aggressive sociopathic behavior may have a karyotype of XYY chromosomes is an example of a possible genetic relationship. The patient with Turner syndrome in whom competent social adaptation is linked closely to an X chromosome of paternal origin is another example. Further, there is no critical evidence to show that deliberate alteration of the familial and social environment or the mental hygienic measures now so popular have ever prevented a neurosis, psychosis, or sociopathy.

It is during the period of late childhood and adolescence, when the personality is least stable, that transient symptoms, many resembling the psychopathologic states of adult life, are most frequent and difficult to interpret. Some of these disorders represent the early signs of autism, schizophrenia, or manic-depressive disease. Others are forerunners of sociopathy. But many of the borderline personality traits have a way of disappearing as adult years are reached, so that one can only surmise that they represented either a maturational delay in the attainment of mature social behavior or were expressions of adolescent turmoil, or what has been called “adolescent adjustment reaction.”

Many issues that have been touched upon in the preceding discussion are considered more fully in the section on psychiatric disorders (Chaps. 56 to 58).

**MENTAL RETARDATION**

The symptom complex of incomplete or insufficient development of mental capacities and associated behavioral abnormalities (variously referred to as mental retardation, mental subnormality, or formerly, *oligophrenia*) combines many of the developmental abnormalities already discussed. Mental retardation stands as the single largest neuropsychiatric disorder in every civilized society. Its overall frequency cannot be stated precisely. Rough estimates are that in a group of children between 9 and 14 years of age, about 2 percent or slightly more will be unable to profit from public education or to adapt socially and, when fully grown up, to live independently. Using any one of a number of indices of social and psychologic failure, two somewhat overlapping groups are recognized: (1) the mildly impaired (IQ 45 to 70), and (2) the severely impaired, corresponding to an IQ below 45. The second group, also called the pathologic mentally retarded, makes up approximately 10 percent of the subnormal population. The more mildly affected first group, which was formerly referred to as the subcultural, psychologic, or familial mentally retarded, is a much larger group. Because of the objectionable implications of the previously used terms idiot, imbecile, and moron, the American Association on Mental Deficiency proposed that the mentally retarded be grouped instead into four categories: (1) those with profound deficiency, incapable of self-care (IQ below 25); (2) those with severe deficiency, incapable of living an independent existence and essentially untrainable (IQ 25 to 39); (3) those with moderate deficiency, trainable to some extent (IQ 40 to 54); and (4) those with mild deficiency, who are impaired but trainable and to some extent educable.

The above terms, while in common use, satisfy neither neurologists nor psychologists because of their generality, embracing as they do any lifelong global deficit in mental capacities. The terms convey no information of the particular type(s) of intellectual impairment, their causes and mechanisms, or their anatomic and pathologic bases. Moreover, they express only one aspect of impaired mental function—the cognitive—and ignore the inadequate development of personality, social adaptation, and behavior. Spe-
types of hereditary mental retardation, but they have not been fully differentiated clinically or pathologically. There being no visible neuropathology, the cases fall into the category of mental retardation without morphologic changes, discussed below.

As an aid to the neurologist, pediatrician, and child neurologist who must assume responsibility for the diagnosis and management of these backward children, the following descriptions may be of value. The more severe forms of mental retardation and the developmental abnormalities and diseases that cause them are discussed in Chap. 38, “Developmental Diseases of the Nervous System.” Here only the milder subcultural forms—i.e., mental retardation without morphologic change—are considered.

**Mental Retardation Without Morphologic Changes**

**Clinical Features** Two clinical types can be recognized based on the adequacy of motor skills that are acquired in parallel with cognitive skills. In the first type, the essential characteristic is that, almost from birth, the infant is delayed in all aspects of development. There is a tendency to sleep more, to be less demanding of nourishment, to move less than normal, and to suck poorly and regurgitate. Parents comment on how good their baby is, how little he troubles them by crying. As the months pass, every expected achievement is late. The baby is usually more hypotonic and turns over, sits unsupported, and walks later than the normal infant. Yet despite these obvious motor delays, there is later no sign of paralysis, ataxia, chorea, or athetosis. These babies do not smile at the usual time and take little notice of the mother or other persons or objects in their environment. They are less attentive to visual and auditory stimuli, to the point where questions may be raised about blindness or deafness. Certain phases of normal development, such as hand regard, may persist beyond the sixth month, when they are normally replaced by other activities. Mouthing (putting everything in the mouth) and slobbering, which should end by 1 year of age, also persist. There are only fleeting signs of interest in toys, and the impersistence of attention becomes increasingly prominent. Vocalizations are scant, often guttural, piercing, or high-pitched and feeble. Babbling is not replaced by attempts at word formation at the usual time.

In the second type, early motor milestones (supporting the head, rolling over, sitting, standing, and walking) may be attained at their normal times, yet the infant is inattentive and slow in learning the usual nursery tricks. It seems as though motor development had somehow escaped the retardation process. There may, however, be aimless overactivity and persistence of rhythmic movements, grinding of the teeth (bruxism), and hypotonia.

Because the developmental sequence of motor function and speech may be normal, even to the point where the baby acquires a few words by the end of the first year, the examiner may be misled into thinking that the mentally retarded infant was at first normal,

---

**Figure 28-4.** Gaussian or bell-shaped curve of intelligence and its skewing by the group of mentally retarded individuals with diseases of the brain. The shaded areas indicate the two groups of mentally retarded. The hump representing the pathologically retarded is purely diagrammatic, illustrating its overlap with the subculturally retarded, discussed in the text and in Chap. 38. When the population plotted is limited to “mental defectives,” a truly bimodal distribution is seen, segregating the two groups of retarded.
and had then deteriorated. In such infants it can even be shown that various test procedures yield lower scores with progressing age (from 3 years onward); this is due not to a decline in ability but to the fact that the tests are not comparable at different times. In the first 3 years, the tests are weighted toward sensorimotor functions and after that toward perception, memory, and concept formation. Interestingly, the development of language depends upon both groups of functions, needing a certain maturation of the auditory and motor apparatus at the start and highly specialized cognitive skills for continued development. These and other aspects of development of speech and language have been considered earlier in this chapter and are commented on further in Chaps. 23 and 38.

Members of both groups of these so-called mildly retarded individuals exhibit a number of noteworthy features that have medical and social implications. Although not overtly dysmorphic and having a normal or low-normal head circumference, they have a high incidence of minor congenital anomalies of the eyes, face, mouth, ears, and hands; they tend to be sickly, and the more severely retarded among them have poor physiques and are often undersized. Deviant behavior occurs frequently (in 7 percent of nonretarded children, in 29 percent of the retarded, and in 58 percent of the epileptic retarded, according to Rutter and Martin). Most often, this behavior takes the form of poor self-control and aggressiveness, especially pronounced in children with temporal lobe epilepsy. Other behavioral disturbances are restlessness, repetitive activity, explosive rage reactions and tantrums, stereotyped play, and the seeking of sensory experiences in unusual ways (Chess and Hassibi). Pica (the compulsive ingestion of nonnutritive substances) is a problem between ages 2 and 4 years of age but is also seen in normal neglected children. The parents of a large proportion of children with all of these abnormal behaviors fall into the lowest segment of the population socially and economically; in other words, the parents may lack the competence to maintain stable homes and to find work, for which reason abandonment, neglect, and child abuse are frequent in this group. The majority of children with deviant behavior need to be placed in special classes or schools, and special measures must be taken to reduce the tendency to truancy, sociopathy, and criminality.

An endless debate is centered on matters of causation—whether these categories of mild retardation are products of a faulty genetic influence, which prevents successful competition and adaptation, or of societal discrimination and lack of training and education coupled with the effects of malnutrition, infections, or other exogenous factors. Surely both environmental and genetic factors are at work, although the relative importance of each has proved difficult to measure (Moser et al).

As mentioned earlier, a pathologic basis for most cases of mild mental retardation has not been established. No visible lesions have been discerned in the brains of this group, unlike those of the severely retarded (pathologic) group, in which malformations and a variety of destructive lesions are obvious in all but 5 to 10 percent of cases. Admittedly, the brains of some of these individuals are about 10 percent underweight, but one cannot at present interpret what this means. It is certain that new methodologies, perhaps relating to neuronal connectivity, will be needed if the cerebra of the subnormal extreme of the general population are to be differentiated from normals. Differences might be expected in terms of the number of neurons in thalamic nuclei and cortex, in dendritic-axonal connectivity, or in synaptic surfaces, elements that are not being assayed by the conventional techniques of tissue neuropathology. The observations of Huttenlocher, who found a marked sparsity of dendritic arborization in Golgi-Cox preparations, and of Purpura, who found an absence of short, thick spines on dendrites of cortical neurons and other abnormalities of dendritic spines, are the first steps in this direction.

Sex linkage is a notable feature of some types of mental retardation. Renpenning and colleagues reported a series of 21 mentally retarded males in three generations of a Canadian family, all free of any congenital malformations and with normal head size, and Turner and coworkers have described a similar Australian series (page 888). No chromosomal abnormality has been found. The fragile-X syndrome (page 889) is another in this group, predominating in males and accounting for about 10 percent of all male retardates. They may be physically normal except for large testicles. Other X-linked forms of mental retardation that have few or no dysmorphic features besides Renpenning and fragile-X syndromes include the Partington, Lowe, Lesch-Nyhan, and Menkes syndromes and adrenoleukodystrophy, each with special characteristics in addition to mental retardation, as discussed in Chaps. 37 and 38. Numerous other X-linked retardation syndromes with accompanying neurologic anomalies have been delineated; for example, the one due to a mutation in the oligophrenin gene, in which there is epilepsy, and another involving cerebellar hypoplasia.

**Diagnosis** Infants should be considered at risk for mental subnormality when there is a family history of mental deficiency, low birth weight in relation to the length of gestation (small-for-date babies), marked prematurity, maternal infection early in pregnancy (especially rubella), and toxemia of pregnancy. In the first few months of life, certain of the behavioral characteristics described above are of value in predicting mental retardation. Prechtl and associates have found that a low Apgar score (especially at 5 min after delivery, Table 28-3), flaccidity, underactivity, and asymmetrical neurologic signs are the earliest indices of subnormality in the infant. Slow habituation of orienting reactions to novel auditory and visual stimuli and the presence of “fine motor deficits” (as previously discussed under “Delays in Motor Development”) are other early warnings of mental retardation.

In the first year or two of life, suspicion of mental retardation is based largely on clinical impression, but it should always be validated by psychometric procedures. Most pediatric neurologists utilize some of the criteria laid down by Gesell and Amatruda or the Denver Developmental Screening Scale, from which a developmental quotient (DQ) is calculated.

For testing of preschool children, the Wechsler Preschool and Primary Scale of Intelligence is used, and for school-age children, the Wechsler Intelligence Scale for Children is preferred. IQ tests for preschoolers must be interpreted with caution, since they have had less predictive validity for school success than the tests that are used after 6 years of age. In general, however, normal scores for age on any of these tests essentially eliminate mental retardation as a cause of poor school achievement and learning disabilities; special cognitive defects may, however, be revealed by low scores on particular subtests. Retarded children not only have low scores but exhibit more scatter of subtest scores. Also, like demented adults, they generally achieve greater success with performance than with verbal items. It is essential that the physician know the conditions of testing, for poor scores may be due to fright, inadequate motivation, lapses in attention, dyslexia, or a subtle auditory or visual defect rather than a developmental lag.

Surprisingly for the neurologist, in this group of retarded children without other neurologic or physical signs, analyses by neu-
robehavioral and psychologic methods have not disclosed the basic fault in nervous functioning. Is there one domain of faulty psychologic function—such as failure of learning, inattentiveness, or faulty perception—that underlies all forms of mental retardation? Or are there several domains, differing from one case to another or one disease to another? Only by the most innovative and sophisticated neuropsychologic studies will answers to such questions be obtained.

The EEG, in addition to exposing asymptomatic seizure activity, shows a high incidence of other abnormalities in the mentally retarded. Presumably this is due to a greater degree of immaturity of the cerebrum at any given age. However, a normal EEG is not infrequent and of relatively little help. Moreover, CT-scanning and MRI have been singularly unhelpful in revealing abnormalities in this group of children.

In the diagnosis of milder grades of retardation, always to be considered are the possible effects of severe malnutrition, neglect and deprivation, chronic systemic disease, iodine deficiency, impaired hearing and vision, and possibly childhood psychosis. Of particular importance is the differentiation of a group of patients who are normal for a variable period after birth and then manifest a progressive decline from disease of the nervous system. This type of disorder is representative of the group of hereditary metabolic and degenerative diseases discussed in Chap. 37. Seizure disorders (and anticonvulsant medications) can impair cerebral function, and several special childhood seizure disorders are associated with a progressive decline in mental function in this group of patients (Chap. 16).

Management Since there is little or no possibility of treating the condition(s) underlying mental retardation and there is no way of restoring function to a nervous system that is developmentally subnormal, the medical objective is to assist in planning for the patient’s training, education, and social and occupational adjustments. As Voltaire remarked long ago, guidance is needed more than education. The parents must be guided in forming realistic attitudes and expectations. Psychiatric and social counseling may help the family to maintain gentle but firm support of the patient so that he can acquire, to the fullest extent possible, self-help skills, self-control, good work habits, and a congenial personality.

Most individuals with an IQ above 60 and no other handicaps can be trained to live an independent life. Special schooling may enable such patients to realize their full potential. Social factors that contribute to underachievement must be sought out and eliminated if possible. Later, there is need for advice about possible occupational attainments.

Great care must be exercised in deciding about institutionalization. Whereas severe degrees of retardation are all too apparent by the first or second year, less severe degrees are difficult to recognize early. As stated above, psychologic tests alone are not trustworthy. The method of assessment suggested many years ago by Fernald still has a ring of soundness. It includes (1) physical examination, (2) family background, (3) developmental history, (4) school progress (grade achieved), (5) performance in schoolwork (tests of reading, arithmetic, etc.), (6) practical knowledge, (7) social behavior, (8) industrial efficiency, (9) moral reactions, and (10) intelligence as measured by psychologic tests. All these data except (5) and (10) can be obtained by a skillful physician during the initial medical and neurologic examination and are used to guide the family in its difficult decisions.

CHAPTER 29
THE NEUROLOGY OF AGING

As indicated in the preceding chapter, standards of growth, development, and maturation provide a frame of reference against which every pathologic process in early life must be viewed. It has been less appreciated, however, that at the other end of the life cycle, neurologic deficits must be judged in a similar way, against a background of normal aging changes (senescence). The earliest of these changes begins long before the acknowledged period of senescence and continues throughout the remainder of life. Not a few medical scientists and physicians believe that all changes in senescence are but the cumulative effects of injury and disease.

Most authors use the terms aging and senescence interchangeably, but some draw a fine semantic distinction between the purely passive and chronologic process of aging and the composite of bodily changes that characterize this process (senescence). Biologists have measured many of these changes. Estimates of the structural and functional decline that accompanies aging from 30 to 80 years are given in Table 29-1. It appears that all structures and functions share in the aging process. Some persons withstand the onslaught of aging far better than others, and this constitutional resistance to the effects of aging seems to be familial. It can also be said that such changes are unrelated to Alzheimer disease and other degenerative diseases but that in general the changes of aging reduce the ability of the organism to recover from virtually any illness or trauma.

Effects of Aging on the Nervous System

Of all the age-related changes, those in the nervous system are of paramount importance. Actors portray old people as being feeble, idle, obstinate, and given to reminiscing and as having tremulous hands, quavering voices, stooped posture, and slow, shuffling steps. In so doing, they have selected some of the most obvious effects of aging on the nervous system. The lay observer, as well as the medical one, often speaks glibly of the changes of advanced age as a kind of second childhood. “Old men are boys again,” said Aristophanes. This view of old age derives from the few resemblances, superficial at best, of the senile dement and the helpless young child.

Neurologic Signs of Aging

Critchley, in 1931 and 1934, drew attention to a number of neurologic abnormalities that he had observed in octogenarians and for which no cause could be discerned other than the effects of aging itself. Several reviews of this subject have appeared subsequently (see especially those of Jenkyn, of Benassi, and of Kokmen and their associates). The most consistent of the neurologic signs of aging are the following:

1. Neuro-ophthalmic signs: progressive smallness of pupils, decreased reactions to light and on accommodation, farsightedness (hyperopia) due to impairment of accommodation (presbyopia), insufficiency of convergence, restricted range of upward conjugate gaze, frequent loss of Bell’s phenomenon, diminished dark adaptation, and increased sensitivity to glare.

2. Progressive perceptive hearing loss (presbycusis), especially for high tones, and commensurate decline in speech discrimination. Mainly these changes are due to a diminution in the number of hair cells in the organ of Corti.

3. Diminution in the sense of smell and, to a lesser extent, of taste (see Chap. 12).

4. Motor signs: reduced speed and amount of motor activity, slowed reaction time, impairment of fine coordination and agility, reduced muscular power (legs more than arms and proximal muscles more than distal ones) and thinness of muscles, particularly the dorsal interossei, thenar, and anterior tibial muscles. A progressive decrease in the number of anterior horn cells is responsible for these changes, as described further on.

5. Changes in tendon reflexes: A depression of tendon reflexes at the ankles in comparison with those at the knees is observed frequently in persons more than 70 years of age, as is a loss of Achilles reflexes in those above 80 years. The snout or palmmontal reflexes, which can be detected in mild form in a small proportion of healthy adults, is a frequent finding in the elderly (in as many as half of normal subjects over 60 years of age, according to Olney). However, other so-called cortical release signs, such as suck and grasp reflexes, are indicative of frontal lobe disease and are not to be expected simply as a result of aging.

6. Impairment or loss of vibratory sense in the toes and ankles. Proprioception, however, is impaired very little or not at all. Thresholds for the perception of cutaneous stimuli increase

with age but require the use of refined methods of testing for their detection. These changes correlate with a loss of sensory fibers on sural nerve biopsy, reduced amplitude of sensory nerve action potentials, and probably loss of dorsal root ganglion cells.

7. The most obvious neurologic aging changes—those of stance, posture, and gait—are fully described in Chap. 7 and further on in this chapter.

The incidence of certain neurologic signs of aging has been determined by Jenkyn and colleagues, based on their examinations of 2029 individuals aged 50 to 93 years. Notable again is the high frequency of snout and glabellar responses, but also limited down-gaze and upgaze in approximately one-third of persons older than 80. These data are summarized in Table 29-2.

With regard to the interesting population of the “oldest old,” over 85 years of age, Kaye and colleagues have reported that deficits in balance, olfaction, and visual pursuit are distinctly worse than in younger elderly persons. Also of interest is the observation by van Exel and colleagues that women in this age group perform better than men on cognitive tests.

Effects of Aging on Memory and Other Cognitive Functions

Probably the most detailed information as to the effects of age on the nervous system comes from the measurement of cognitive functions. In the course of standardization of the original Wechsler-Bellevue Intelligence Scale (1955), cross-sectional studies of large samples of the population indicated that there was a steady decline in cognitive function starting at 30 years of age and progressing into the senium. Apparently all forms of cognitive function partake of this decline—although in general certain elements of the verbal scale (vocabulary, fund of information, and comprehension) withstand the effects of aging better than those of the performance scale (block design, reversal of digits, picture arrangement, object assembly, and the digit symbol task).

However, the concept of a linear regression of cognitive function with aging has had to be modified in the light of subsequent longitudinal studies. If the same individual is examined over a period of many years, there is virtually no decline in his performance as measured by tests of verbal function until 60 years of age. Beyond this age, verbal intelligence does decline, but very slowly—by an average of less than 5 percent through the seventh decade and less than 10 percent through the eighth decade (Schaie and Hertzog). Also, in a series of 460 community-dwelling individuals (55 to 95 years of age) studied by Smith and coworkers at the Mayo Clinic, there was no significant decline with age in verbal memory and in registration-attention; similar results were found by Peterson and colleagues in 161 normal, community dwelling individuals 62 to 100 years of age. The most definite effects of age were in learning and memory and in problem solving—cognitive impairments probably attributable to a progressive reduction in the speed of processing information. The latter is reflected in the slowing of event-related evoked potentials and by a number of special psychologic tests (see Verhaeghen et al).

As regards these cognitive functions, it hardly needs to be pointed out that the ability to memorize, acquire and retain new information, recall names, and avoid distraction once set on a course of action diminishes with advancing age, particularly in those more than 70 years old. Moreover, memory function may be disturbed in this way despite the relative intactness of other intellectual abilities. Characteristically, there is difficulty with recall of a name or the specific date of an experience (“episodic” memory) despite a preservation of memory for the experience itself or for the many features of a person whose name is momentarily elusive (“tip-of-the-tongue syndrome”). Also characteristic is an inconsistent retrieval of the lost name or information at a later date. It has been found, however, that if older persons are allowed to learn new material very well, until no errors are made, they forget this information at a rate similar to that of younger individuals (see review by Albers).

Kral, who first wrote informatively on this type of memory disturbance, referred to it as benign senescent forgetfulness. He pointed out that such a memory disturbance, in distinction to that of Alzheimer disease, worsens very little or not at all over a period of many years and does not interfere significantly with the person’s work performance or activities of daily living. More recently, Crook and coworkers have refined the diagnostic criteria for senescent forgetfulness and have proposed a new term—age-associated memory impairment (AAMI). The diagnostic criteria for the latter disorder include age of 50 years or older, a subjective sense of decline in memory, impaired performance on standard tests of memory function (at least one SD below the mean), and absence of any other signs of dementia.

The current terminology is minimal cognitive impairment, but there has been increasing recognition that Kral’s original notion of a benign condition may have been incorrect and that cognitive decline in later years may be a risk factor for Alzheimer disease.

In judging the degree of cognitive decline, several abbreviated tests of mental status have been developed and are of practical value (Kokmen et al; Folstein et al) in that they can be given at the bedside in 5 to 10 min. Repetition of spoken items, such as a series of digits, orientation as to place and time, capacity to learn and to retain several items, tests of arithmetic and calculation (concentration), and specific tests for memory (particularly tests of delayed recall or forgetfulness) reveal that normal aging persons invariably perform at a significantly higher level than patients with Alzheimer disease, and these tests readily discriminate between the two groups (Larrabee et al). With regard to performance on the mini-mental status examination (Table 21-6, Folstein and colleagues), a study by Crum and associates of a large urban population indicates a median score of 19–20 for individuals over age 80 who have a

fourth grade education and 27 for those with a college education (out of maximum score of 30).

The foregoing effects of age on mental abilities are extremely variable. Some 70-year-olds perform better on psychologic testing than some “normal” 20-year-olds. And a few individuals retain exceptional mental power and perform creative work until late life. Verdi, for example, composed Otello at the age of 73 and Falstaff at 79. Humboldt wrote the five volumes of his Kosmos between the ages of 76 and 89 years; Goethe produced the second part of Faust when he was more than 70 years old; Galileo, Laplace, and Sherrington continued to make scientific contributions in their eighth decades; and Picasso continued to paint in his nineties. It must be pointed out, however, that these accomplishments were essentially continuations of lines of endeavor that had been initiated in early adult life. Indeed, little that is new and original is started after the 40th year. High intelligence, well-organized work habits, and sound judgment compensate for many of the progressive shortcomings of old age.

**Personality Changes in the Aged** These are less easily measured than cognitive functions, but certain trends are nevertheless observable and may seriously disturb the lives of aged persons and those around them. Many old people become more opinionated, repetitive, self-centered, and rigid and conservative in their thinking; the opposite qualities—undue pliancy, vacillation, and the uncritical acceptance of ideas—are observed in others. Often these changes can be recognized as exaggerations of lifelong personality traits. Elderly persons tend to become increasingly cautious; many of them seem to lack self-confidence and require a strong probability of success before undertaking certain tasks. These changes may impair their performance on psychologic testing. Kallman’s studies of senescent monozygotic twins suggest that genetic factors are more important than environmental ones in molding these traits.

One of the weaknesses of studies of the aged has been the bias in selection of patients. Many of the reported observations have been made in cohorts of individuals residing in nursing homes. Studies of functionally intact old people of comparable age and living independently, such as those of Kokmen and of Benassi and their colleagues, reveal fewer deficits, consisting mainly of forgetfulness of names, smallness of pupils, restriction of convergence and upward conjugate gaze, diminished Achilles reflexes and vibratory sense in the feet, stooped posture, and impairments of balance, agility, and gait (as mentioned earlier and below).

**Effects of Aging on Stance and Gait and Related Motor Impairments** (See also Chap. 7)

These are among the most conspicuous manifestations of the aging process. Motor agility actually begins to decline in early adult life, even by the 30th year; it seems related to a gradual decrease in neuromuscular control as well as to changes in joints and other structures. The reality of this motor decrement is best appreciated by professional athletes who retire at age 35 or thereabout because their legs give out and cannot be restored to their maximal condition by training. They cannot run as well as younger athletes, even though the strength and coordination of their arms is relatively preserved. More subtle and imperceptibly evolving changes in stance and gait are ubiquitous features of aging (Chap. 7). Gradually the steps shorten, walking becomes slower, and there is a tendency to stoop. The old soldier must repeatedly remind himself to maintain an erect bearing. The older person becomes less confident and more cautious in walking and habitually touches the handrail in descending stairs, to prevent a misstep.

To be distinguished from the ubiquitous and subtle changes in gait of the “normal” aged population is a more rapidly evolving and inordinate deterioration of gait that affects a small proportion of the aging population while they remain relatively competent in other ways. In all likelihood, this latter disorder represents an age-related degenerative disease of the brain, since most instances of it are sooner or later accompanied by mental changes. The basis of this gait disorder is probably a combined frontal lobe-basal ganglionic degeneration, the anatomy of which has never been fully clarified, as discussed on page 106. However, in many of such patients we have observed, there is no disproportionate atrophy or reduction of blood flow in the frontal lobes, making the cause of the gait disorder obscure. It has also been postulated that age-related changes in the substantia nigra are the cause of the parkinsonian appearance of the gait of the aged, but it does not respond to L-dopa or to any other therapeutic measure. The main differential diagnostic consideration is normal-pressure hydrocephalus, correctable by a ventriculoperitoneal shunt, which accounts for the gait disorder of a sizable group of these elderly patients, as discussed in Chaps. 7 and 30 (Fisher). Parkinson disease is yet another potentially treatable cause of walking difficulty. Progressive supranuclear palsy is a degenerative process in which gait and stability are affected early and profoundly.

Urinary incontinence, defined as a state in which “involuntary loss of urine is a social or hygienic problem and is objectively demonstrated,” is a surprisingly common occurrence in the elderly (Wells and Diokno). Doubtless this complex of motor impairments is based on the aforementioned neuronal losses in the spinal cord, cerebellum, and cerebrum.

**Falls in the Elderly** Among elderly persons without apparent neurologic disease, falls constitute a major health problem. About 30 percent suffer one or more falls each year; this figure rises to 40 percent among those over the age of 80 and to more than 50 percent among elderly persons living in nursing homes. According to Tinetti and colleagues, 10 to 15 percent of falls in the elderly result in fractures and other serious injuries; they are reportedly an underlying cause of about 9500 deaths annually in the United States.

Several factors, some mentioned above in regard to deterioration of gait, are responsible for the inordinately high rate of falling among older persons. Impairment of visual function and particularly of vestibular function with normal aging are important contributors. In a group of 34 elderly patients who were free of neurologic disease, postural hypotension, and leg deformities, Weiner and colleagues found a moderate or severe degree of postural reflex impairment in two-thirds. The failure to make rapid postural adjustments, which is a product of aging alone, accounts for the occurrence of falls in the course of usual activities such as walking, changing position, or descending stairs. Postural hypotension, often due to antihypertensive agents and the use of sedative drugs, is another important cause of falling in the elderly (page 464).

Of course, falling is an even more prominent feature of certain age-related neurologic diseases: stroke, Parkinson disease, normal-pressure hydrocephalus, and progressive supranuclear palsy, among others.

**Other Restricted Motor Abnormalities in the Aged** These are too numerous to be more than catalogued. They reflect the many
ways in which the motor system can deteriorate. Compulsive, repetitive movements are the most frequent: mouthing movements, stereotyped grimacing, protrusion of the tongue, side-to-side or to-and-fro tremor of the head, odd vocalizations such as sniffling, snorting, and bleating. In some respects these disorders resemble tics (quasivoluntary movements to relieve tension), but careful observation shows that they are not really voluntary. Haloperidol and other drugs of this class have an unpredictable therapeutic effect, seeming at times to benefit the patient only by the superimposition of a drug-induced rigidity.

Old age is thought always to carry a liability to tremulousness, and indeed, one sees this association with some frequency. The head, chin, or hands tremble and the voice quavers, yet there is not the usual slowness and poverty of movement, facial impassivity, or flexed posture that would stamp the condition as parkinsonian. Some instances of tremor are clearly familial, having appeared or worsened only late in life. However, the relation of tremulousness to senility is sometimes open to doubt. Charcot, in a review of over 2000 elderly inhabitants of the Sâpètries, could find only about 30 with tremor. Some cases probably represent the exaggeration or emergence of essential tremor, but many cases cannot be explained on this basis.

Spastic or spasmodic dysphonia, a disorder of middle and late life characterized by spasm of all the throat muscles on attempted speech, is discussed on page 428. Blepharoclonus or blepharo-spasms, an involuntary movement of the eyelids, is also described on page 93.

**Morphologic and Physiologic Changes in the Aging Nervous System**

These have never been fully established. From the third decade of life to the beginning of the tenth decade, the average decline in weight of the male brain is from 1394 to 1161 g, a loss of 233 g. The pace of this change, very gradual at first, accelerates during the sixth or seventh decades. The loss of brain weight, which correlates roughly with enlargement of the lateral ventricles and widening of the sulci, is presumably the result of neuronal degeneration and replacement gliosis, although this has not been proved. The counting of cerebrocortical neurons is fraught with technical difficulties, even with the use of computer-assisted automated techniques (see the critical review of neuron-counting studies by Coleman and Flood). Most studies, point to a depletion of the neuronal population in the neocortex, especially evident in the seventh, eighth, and ninth decades.

Cell loss in the limbic system (hippocampus, parahippocampal and cingulate gyri) is of special interest in regard to memory. Ball, who measured the neuronal loss in the hippocampus, recorded a linear decrease of 27 percent between 45 and 95 years of age. Dam reported a similar degree of cell loss and replacement gliosis. These changes seem to proceed without relationship to Alzheimer neurofibrillary changes and senile plaques (Kemper). However, recent morphologic work, summarized by Albers and also by Morrison and Hof, suggests that cerebral cell loss with aging is less pronounced than previously thought. Furthermore, as pointed out by Morrison, the hippocampus may have only minimal cell loss. Moreover, this is partially a result of neurogenesis in this region. Brain shrinkage is accounted for in part by the reduction in size of large neurons, not their disappearance. There is a more substantial reduction in neuronal number in the substantia nigra, locus ceruleus, and basal forebrain nuclei. It may be possible to differentiate normal aging from disease in the medial temporal lobe by distinguishing between cell loss in specific regions (see Small), but novel techniques are required.

Mueller and colleagues have utilized quantitative volumetric MRI techniques to examine a cohort of 46 nondemented elderly individuals. They found small, constant rates of loss of brain volume with aging. Moreover, the rates of volume loss in the last decades of life were no greater than in the immediately preceding decades—suggesting that large changes in brain volume in the elderly are attributable to the dementing diseases common to this age period. Serial MRIs of elderly persons have been found by Rusinick and colleagues to predict which individuals will develop disproportionate atrophy and dementia. In particular, hippocampal atrophy increases at the rate of less than 2 percent per year in healthy elderly people, in comparison to 4 to 8 percent a year in early Alzheimer disease. This longitudinal method of study is more sensitive than cross-sectional populations studies.

Among lumbosacral anterior horn cells, sensory ganglion cells, and putaminal and Purkinje cells, neuronal loss amounts to at most 25 percent between youth and old age. Not all neuronal groups are equally susceptible. For example, the locus ceruleus and substantia nigra, as already commented, lose about 35 percent of their neurons, whereas the vestibular nuclei and inferior olives maintain a fairly constant number of cells throughout life. A very subtle loss, decade by decade, of the major systems of nerve cells and myelinated fibers of the spinal cord has been demonstrated by Morrison. This accelerates after the age of 60 (Tomlinson and Irving).

As described above, in normal aging, there is a gradual decline in memory and in some cognitive functions. In light of the studies just summarized, it is no longer considered that these changes can be ascribed simply to neuronal loss. Rather, they are probably due at least in part to alterations in synaptic connectivity within critical cortical structures.

Scheibel and coworkers have described a loss of neuronal dendrites in the aging brain, particularly the horizontal dendrites of the third and fifth layers of the neocortex. However, the Golgi method, which was used in these studies, is difficult to interpret because of artifacts. The morphometric studies of Buell and Coleman have shown that the surviving neurons actually exhibit expanded dendritic trees, suggesting that even aging neurons have the capacity to react to cell loss by developing new synapses. Overall, the evidence suggests shrinkage of cells.

With advancing age, there is an increasing tendency for neuritic (amyloid and neurofibrillary) plaques to appear in the brains of nondemented individuals. At first the plaques appear in the hippocampus and parahippocampus, but later they become more widespread. These are loose aggregates of amorphous argyrophilic material containing amyloid. They occur in increasing numbers with advancing age; by the end of the ninth decade of life, few brains are without them. However, as shown by Tomlinson and colleagues, relatively fewer plaques are present in the brains of mentally intact old people, in contrast to the large numbers in those with Alzheimer disease. Even more impressive is the correlation of neurofibrillary tangles and Alzheimer disease. Very few such tangles are found in the brains of mentally sound individuals, and such as are found are essentially confined to the hippocampus and adjacent entorhinal cortex. By contrast, neurofibrillary tangles are far more abundant and diffusely distributed in patients with Alzheimer disease.

The view is often expressed that neuritic plaques and Alzhei-
mer type of neurofibrillar changes simply represent an acceleration of the natural aging process in the brain. We are more inclined to the idea that the plaques and neurofibrillary changes represent an acquired age-linked disease, analogous in this respect to certain cerebrovascular diseases. In support of this latter view are several observations. First, Homo sapiens is the only animal species in which Alzheimer neurofibrillary changes and neuritic plaques are regularly found in the aging brain. A few plaque-like structures (but no neurofibrillary changes) have been seen occasionally in old dogs and monkeys but not in mice or rats. It seems unbiologic that human aging should differ from that of all other animal species. Second, some of the most severe forms of Alzheimer disease occur in middle adult life, long before the senium. Third, these histopathologic changes in variable proportion occur in a number of other diseases unrelated to aging, such as dementia pugilistica (“punch-drunk” state), Down syndrome, postencephalitic Parkinson disease, and progressive supranuclear palsy. Fourth, neurofibrillary tangles can be reproduced in the experimental animal by such toxins as aluminum, vincristine, vinblastine, and colchicine. Finally, a small proportion of Alzheimer cases are definitely familial. Alzheimer disease is therefore more appropriately considered with degenerative diseases (see Chap. 39, where the entire subject is discussed further).

Virtually every molecular structure within the cell is subject to age-related biochemical modifications, such as the formation of carbonyl proteins, glycation of sugars, and oxidative changes in lipids. Some of these subcellular phenomena contribute to the aging process (see Smith CD et al and Mrak et al for details), as do the cumulative mitochondrial DNA mutations and shortened lengths of the telomeres. Among the visible biochemical alterations is an increasing accumulation of lipofuscin granules in the cytoplasm of neurons, sometimes extreme in degree. Also, there is an age-related neuronal accumulation of iron and other pigment bodies. Granulovacuolar changes are a regular finding in aging hippocampi, regardless of the mental state of the individual. The accumulation of amyloid-containing concretions (corpora amylaceae) around nerve roots and diffusely in the subpial space is yet another aging effect.

Cerebral atherosclerosis is, of course, a frequent finding in the elderly, but it does not parallel aging with any degree of precision, being severe in some 30- to 40-year-old individuals and practically absent in some octogenarians. In the normotensive individual, it tends to occur in scattered, discrete plaques mostly in the aorta and cervical arteries (carotid bifurcation and higher segments), proximal middle cerebral arteries, and at the vertebrobasilar junction and basilar portions of the cerebral arterial system. In the hypertensive and diabetic, it is more diffuse and extends into finer branches of the cerebral and cerebellar arteries. One or more cerebral ischemic softening (infarcts) are found in about 25 percent of all individuals more than 70 years of age who have been carefully examined postmortem. In addition to atherosclerotic disease, the basilar arteries become somewhat larger and more tortuous and opaque in the elderly.

Cerebral blood flow has been extensively investigated in the elderly population. Most studies have shown that flow declines with age and that the cerebral metabolic rate declines in parallel. There is also an age-related increase in cerebrovascular resistance. Declines in flow are somewhat greater in the cortex than in white matter and greater in prefrontal regions than in other parts of the hemispheres. Obrist demonstrated a 28 percent reduction in cerebral flow by age 80. It is noteworthy, however, that every cohort of elderly persons tested in this way contained a significant proportion in which cerebral blood flow was equivalent to that in young control subjects. In fact, in a group of 72-year-old men rigorously selected on the basis of freedom from disease, Sokoloff demonstrated that cerebral blood flow and oxygen consumption did not differ from those of normal men 22 years of age. Cerebral glucose metabolism was reduced in all the elderly subjects, however.

With advancing age there is a general tendency for the electroencephalogram (EEG) to show a slowing of the alpha rhythm, an increase in beta activity, a decline in the percentage of slow-wave sleep, and an increasing intrusion of theta rhythms, particularly over the temporal lobes. There are large individual differences, however.

With respect to the neurotransmitters, it is generally agreed that the concentrations of acetylcholine, norepinephrine, and dopamine decline in the course of normal aging. Also, the concentration of gamma-aminobutyric acid (GABA) has been shown to decline with age, particularly in the frontal cortex (Spokes et al). Analyses of postmortem human and animal brains have failed to demonstrate a decline with age in the concentration of serotonin or its metabolites (McEntee and Crook). Accurate assessment of other neurotransmitters has been more difficult because of their marked lability in postmortem material. Data from experiments in rats suggest that the glutamate content of the brain and the number of N-methyl-D-aspartate (NMDA) receptors diminish with age, but the functional significance of this finding is unclear. Unlike the case in Alzheimer disease, normal aging is associated with only slight and inconsistent abnormalities of cholinergic innervation of the hippocampus and cortex. This is true also of the acetylcholine content and the activity of choline acetyltransferase (the synthesizing enzyme of acetylcholine) in these regions and the number of cholinergic neurons in the nucleus basalis of Meynert (substantia innominata) and other nuclei of the basal forebrain (Decker). Again, the significance of these changes is difficult to judge. They probably reflect the depletion of cells that occurs with aging. The topics of cholinergic and glutamatergic function in the aging brain have been critically reviewed by McEntee and Crook.

Aging Changes in Muscles and Nerves

With advancing age, skeletal muscles lose cells (fibers) and undergo a gradual reduction in their weight more or less parallel to that of the brain. Atrophy of muscles and diminution in peak power and endurance are clinical expressions of these changes. Many processes contribute to this age-dependent loss of lean muscle mass, described as sarcopenia. These include decreased physical activity; diminished appetite associated with loss of smell and elevated levels of cholecystokinin, a satiety hormone; other endocrine changes such as diminished levels of growth hormone and androgens; and (as in the brain) the accumulation of subcellular defects such as nuclear and mitochondrial DNA mutations alluded to earlier. Moreover, with aging, the slow loss of motor neurons contributes to a component of denervation atrophy. Our own observations of neuropathologic material indicate that the wasting involves several processes, some principally myopathic and others relating to disuse or denervation, from loss of motor neurons. In this material, denervation atrophy of the gastrocnemius muscles was found in 80 percent of individuals over 70 years of age. The lost muscle fibers are gradually replaced by endomysial connective tissue and fat cells. The surviving fibers are generally thinner than normal (pos-
sibly due to disuse atrophy), but some enlarge, resulting in a wider than normal range of fiber size. Groups of fibers all at the same stage of atrophy undoubtedly relate to loss of motor innervation. The reduction in conduction velocity and decrease in amplitude of motor nerve potentials and, to a greater extent, of sensory nerves in the aged may be taken as other indices of loss of motor and sensory axons. All these changes are more marked in the legs than elsewhere. However, when Roos and colleagues examined the contractile speed and firing rates of the quadriiceps muscle in young men and compared them to those of men close to 80 years old, they found little difference despite a 50 percent reduction in the maximum voluntary contraction force developed by the muscle in the older men.

It has been repeatedly observed that age is an important prognostic factor in a large number of human diseases. This effect is very evident, for example, in the markedly slower and less complete recovery from Guillain-Barré polyneuropathy in older age groups compared with younger ones. One presumes that the structural changes of aging in peripheral nerves limit the degree of myelin regeneration and lower the threshold for failure of electrical transmission.

**GERONTOLOGIC NEUROLOGY**

Gerontology is defined as the study of aging and gerontologic neurology as the study of the effects of aging—both of aging itself and of the age-related diseases—on the nervous system. In comparison to pediatric neurology, these disciplines have not aroused much interest. The young physician is more excited by acute disease than by the seemingly immutable changes due to aging and is inclined to question whether medicine has a significant role to play in treating the neurologic disorders of the elderly. The authors would answer this question affirmatively for the simple reason that a majority of all neurologic patients seen in practice are elderly, especially if one includes those with vascular diseases of the brain. Furthermore, many of their diseases are preventable or therapeutically controllable. Some of the age-related chemical deficiencies (i.e., vitamin B deficiencies, diabetes mellitus) and many of the common restricted involutional changes (presbyopia, etc.) can be corrected. Others can even be turned into assets; the forgetfulness of the aged and their deafness may serve to excuse many of their shortcomings and to spare them effort and annoyance. And always, there is the need to counsel the elderly patient on matters pertaining to health and daily activities. This was appreciated even in the time of Cicero, who, in his *De Senectute*, urged the practice of moderation in exercise and giving due attention to the mind, which must be kept active—or, like a lamp that is not supplied with oil, it will grow dim.

As medical science and public health measures have brought diseases of aging and other diseases under control, the number of elderly persons has increased and will continue to do so. The U.S. Census Bureau has estimated that in the year 2000 there were 31 million persons over the age of 65 in the United States and that 13 million of them were more than 75 years old. As the number of elderly increases, the need to look after them will occupy more and more of the energies of physicians and the resources of society at large.

Once an old person declines physically and mentally to a vegetative state, the issue of euthanasia and all the ethical problems it entails will arise from time to time. The authors reject this solution while committing themselves to measures that prevent pain and suffering.

PART 4

MAJOR CATEGORIES OF NEUROLOGIC DISEASE
CHAPTER 30
DISTURBANCES OF CEREBROSPINAL FLUID AND ITS CIRCULATION
Including Hydrocephalus, Pseudotumor Cerebri, and Low-Pressure Syndromes

In many chapters to follow, reference will be made to the ways in which the cerebrospinal fluid (CSF) reflects the basic pathologic processes in a wide variety of inflammatory and infectious, metabolic, neoplastic, demyelinating, and degenerative diseases. The CSF alterations in these varied circumstances raise so many interesting and important problems that we consider it worthwhile to discuss in one place the mechanisms involved in the formation, circulation, and absorption of the CSF, particularly as they pertain to increased intracranial pressure (ICP). Also to be considered in this chapter are hydrocephalus, pseudotumor cerebri, and syndromes produced by greatly reduced pressure in the CSF compartment. In all of these conditions, the primary abnormalities are those of the CSF and its circulation. Examination of the CSF as a diagnostic aid in neurology was discussed in Chap. 2; the primary infective and non-infective inflammatory reactions of the pia-arachnoid (leptomeninges) and ependyma of the ventricles are considered in Chap. 32.

A few historical points call to mind that our knowledge of the physiology, chemistry, and cytology of the CSF is relatively recent. Although the lumbar puncture was introduced by Quincke in 1891, it was not until 1912 that Mestrezat made the first correlations between disease processes and the cellular and chemical changes in the CSF. In 1937, Merritt and Fremont-Smith published their classic monograph on the CSF changes in all types of disease. Most of our knowledge of CSF cytology has accumulated since the late 1950s, when membrane filtration techniques (particularly the cellulose ester or Millipore filter) were introduced. The studies of Dandy (1919) and of Weed (1935) provided the basis of our knowledge of CSF formation, circulation, and absorption. There followed the important studies of Pappenheimer and of Ames and their colleagues, and the monographs of Fishman and of Davson and coworkers, which are important recent contributions. The cytology of the CSF is informatively summarized in the monographs of Du-fresne and Den Hartog-Jager (see Chap. 2 for references).

PHYSIOLOGY OF THE CEREBROSPINAL FLUID

The primary function of the CSF appears to be a mechanical one; it serves as a kind of water jacket for the spinal cord and brain, protecting them from potentially injurious blows to the spinal column and skull and acute changes in venous pressure. Also, it provides the brain with buoyancy. As pointed out by Fishman, the 1500-g brain, which has a water content of approximately 80 percent, weighs only 50 g when suspended in CSF, so the brain virtually floats in its CSF jacket. Many of the physiologic and chemical mechanisms described below are committed to maintaining the relatively constant volume-pressure relationships of the CSF. In addition, since the brain and spinal cord have no lymphatic channels, the CSF, through its “sink action” (see below), serves to remove the waste products of cerebral metabolism, the main ones being CO₂, lactate, and hydrogen ions. The composition of the CSF is maintained within narrow limits, despite major alterations in the blood; thus the CSF, along with the intercellular fluid of the brain, helps to preserve a stable chemical environment for neurons and their myelinated fibers. There is no reason to believe that the CSF is actively involved in the metabolism of the cells of the brain and spinal cord.

In the adult, the average intracranial volume is 1700 mL; the volume of the brain is from 1200 to 1400 mL, CSF volume ranges from 70 to 160 mL (mean, 104), and that of blood is about 150 mL. In addition, the spinal subarachnoid space contains 10 to 20 mL of CSF. Thus, at most, the CSF occupies somewhat less than 10 percent of the intracranial and intraspinal spaces. The proportion of CSF in the ventricles and cisternae and in the subarachnoid spaces between the cerebral hemispheres and the sulci varies with age. These variations have been plotted in computed tomography (CT) scans by Meese and coworkers; the distance between the caudate nuclei at the anterior horns gradually widens by approximately 1.0 to 1.5 cm, and the width of the third ventricle increases from 3 to 6 mm by age 60.

Formation The introduction of the ventriculocisternal perfusion technique by Pappenheimer and colleagues made possible accurate measurement of the rates of formation and absorption of the CSF. It is now established that the average rate of CSF formation is 21 to 22 mL/h (0.35 mL/min), or approximately 500 mL/day. The CSF as a whole is therefore renewed four or five times daily.

The choroid plexuses, located in the floor of the lateral, third, and fourth ventricles, are the main sites of CSF formation (some CSF is formed even after the choroid plexuses are removed). The thin-walled vessels of the plexuses allow passive diffusion of substances from the blood plasma into the extracellular space surrounding choroid cells. The choroidal epithelial cells, like other secretory epithelia, contain organelles, indicating their capacity for an energy-dependent secretory function, i.e., “active transport.” The blood vessels in the subependymal regions and the pia also contribute to the CSF, and some substances enter the CSF as readily from the meninges as from the choroid plexuses. Thus, electrolytes equilibrate with the CSF at all points in the ventricular and subarachnoid spaces, and the same is true of glucose. The transport of sodium, the main cation of the CSF, is accomplished by the action of a sodium-potassium-ion exchange pump at the apical surface of the choroid plexus cells, the energy for which is supplied by adenosine triphosphate; drugs that inhibit the ATP system reduce CSF
formation (Cutler and Spertell). Electrolytes enter the ventricles somewhat more readily than they enter the subarachnoid space (water does the opposite). It is also known that the penetration of certain drugs and metabolites is in direct relation to their lipid solubility. Ionized compounds, such as hexoses and amino acids, being relatively insoluble in lipids, enter the CSF slowly unless facilitated by a membrane transport system. This type of facilitated (carrier) diffusion is stereospecific; i.e., the carrier (a specific protein or protolipid) binds only with a solute having a specific configuration and carries it across the membrane, where it is released into the CSF and intercellular fluid.

Diffusion gradients appear to determine the entry of serum proteins into the CSF and also the exchanges of CO₂. Water and sodium diffuse as readily from blood to CSF and intercellular spaces as in the reverse direction. This explains the rapid effects of intravenously injected hypotonic and hypertonic fluids.

Studies using radioisotopic tracer techniques have shown that the various constituents of the CSF (see Table 2-1) are in dynamic equilibrium with the blood. Similarly, CSF in the ventricles and subarachnoid spaces is in equilibrium with the intercellular fluid of the brain, spinal cord, and olfactory and optic nerves. Certain structures that were thought to maintain this equilibrium—namely, _the blood-CSF barrier and brain CSF barrier_—are now subsumed under the term _blood-brain barrier_, which is used to designate all of the interfaces between blood, brain, and CSF. The site of the barrier varies for the different plasma constituents. One is the endothelium of the choroidal and brain capillaries; another is the plasma membrane and adventitia (Rouget cells) of these vessels; a third is the pericapillary foot processes of astrocytes. Large molecules such as albumin are prevented from entry by the capillary endothelium, and this is also true for such molecules as are bound to albumin, e.g., aniline dyes (trypan blue), bilirubin, and many drugs. Other smaller molecules are blocked from entering the brain by the capillary plasma membrane or astrocytes.

The various substances formed in the nervous system during its metabolic activity diffuse rapidly into the CSF. Thus, the CSF has a kind of “sink action,” to use Davson’s term, by which the products of brain metabolism are removed into the bloodstream as CSF is absorbed.

**Circulation** Harvey Cushing aptly termed the CSF the “third circulation,” comparable to that of the blood and lymph. From its principal site of formation in the choroid plexus of the lateral ventricles, the CSF flows downward through the third ventricle, aqueduct, fourth ventricle, and foramen of Magendie (medially) and Luschka (laterally) at the base of the medulla, to the perimedullary and perisphenoid subarachnoid spaces, thence around the brainstem and rostrally to the basal and ambient cisterns, through the tentorial aperture, and finally to the lateral and superior surfaces of the cerebral hemispheres, where most of it is absorbed (Fig. 30-1). The pressure is highest in the ventricles and diminishes successively along the subarachnoid pathways. Arterial pulsations of the choroid plexuses help drive the fluid from the ventricular system.

The spinal fluid is everywhere in contact with the extracellular fluid of the brain and spinal cord, but the extent of bulk flow of the CSF through the brain parenchyma is small under normal conditions. The periventricular tissues offer considerable resistance to the entrance of CSF, and although the pressure difference between the ventricles and the subarachnoid spaces (transmantine pressure) is only slightly above zero, the open ventricular-foraminal-subarachnoid pathway directs the bulk of CSF flow in this direction.

Only if this conduit is obstructed does the transmantine pressure rise, compressing the periventricular tissues and leading to ventricular enlargement and transependymal flow of CSF.

**Absorption** Absorption of CSF is through the arachnoid villi. These are microscopic excrescences of arachnoid membrane that penetrate the dura and protrude into the superior sagittal sinus and other venous structures. Multiple villi are aggregated in these locations to form the pacchionian granulations or bodies, some of them large enough to indent the inner table of the calvarium. The arachnoid villi, most numerous on both sides of the superior sagittal sinus, are present at the base of the brain and around the spinal cord roots and have been thought to act as functional valves that permit unidirectional “bulk flow” of CSF into the vascular lumen. However, electron microscopic studies have shown that the arachnoid villi have a continuous membranous covering. This layer is extremely thin, and CSF passes through the villi at a linearly increasing rate as CSF pressures rise above 68 mmH₂O. This passive route is not the only manner in which CSF water and other contents are transported. Tripathi and Tripathi, in serial electron micrographs, found that the mesothelial cells of the arachnoid villus contain small cytoplasmic vacuoles that are capable of transcellular bulk transport. Certain substances, such as penicillin and organic acids and bases, are also absorbed by cells of the choroid plexus; the bidirectional action of these cells resembles that of the tubule cells of the kidneys. Some substances have been shown in pathologic specimens to pass between the ependymal cells of the ventricles and to enter subependymal capillaries and venules.

By infusing and withdrawing CSF under controlled circumstances, the resistance to CSF absorption and its rate of replacement can be calculated. The resistance to the passage of CSF into the

With ventricular obstruction. C. With obstruction at or near the points of outlet of the CSF. D. With obstruction of the venous outflow. (Redrawn by permission from Foley.)
venous system has been termed $R_v$ and can be expressed in terms similar to Ohm’s law ($E = IR$); the voltage ($E$) reflects the difference in pressure between the CSF and the venous system ($P_{CSF} - P_v$), which drives CSF into the dural sinuses, and the equivalent of electrical current, termed $I_v$, represents the flow rate of CSF. In the steady state, this is equal to the rate of CSF production (0.3 mL/min). $R_v$, the resistance to absorption, which under normal circumstances is approximately 2.5, understandably rises when there is a blockage in the CSF circulation. The equation for CSF absorption can be expressed as $P_{CSF} - P_v = I_v \times R_v$. When rearranged, therefore, $P_{CSF} = P_v + I_v \times R_v$, since the product of $I_v \times R_v$ is only 0.8 mmHg, it can be appreciated that the main contribution to CSF pressure—as, for example, measured by spinal puncture—is the venous pressure, $P_v$. Restated, CSF and ICP pressures, which are in equilibrium, are derived largely from transmitted vascular pressures and not from CSF outflow resistance. In pathologic conditions such as bacterial meningitis and subarachnoid hemorrhage, $R_v$ may rise to levels that impede CSF circulation and cause hydrocephalus.

Volume and Pressure

In the recumbent position, ICP and consequently CSF pressure measured by lumbar puncture is normally about 8 mmHg or 110 mmH$_2$O (1 mmHg equals 13.7 mmH$_2$O). As the head and trunk are progressively elevated, the weight of the column of CSF is added incrementally to the pressure in the lumbar subarachnoid space, and the ICP drops correspondingly, so that it is close to zero in the standing position. As described above, the CSF pressure is in equilibrium with the capillary or prevenous vascular pressure, which is influenced mainly by circulatory changes that alter arteriolar tone. Rises in systemic arterial pressure cause little or no increase of pressure at the capillary level (because of autoregulation) and hence little increase in CSF pressure.

The inhalation or retention of CO$_2$ raises the blood PCO$_2$ and correspondingly decreases the pH of the CSF. By a mechanism that is not fully understood, this acidification of the CSF acts as a potent cerebral vasodilator, causing an increase in cerebral blood flow and leading to intracranial hypertension. Hyperventilation, which reduces PCO$_2$, has the opposite effect—i.e., it increases the pH and the cerebral vascular resistance and thereby decreases CSF pressure; this maneuver of lowering the arterial CO$_2$ content by hyperventilation is utilized in the treatment of acutely raised ICP.

In contrast to the limited effect caused by changes in arterial blood pressure, increased venous pressure exerts an almost immediate effect on CSF pressure by increasing the volume of blood in the cerebral veins, venules, and dural sinuses. If jugular veins are compressed, there is a rise of intracranial pressure that is transmitted to the lumbar subarachnoid space (unless there is a spinal subarachnoid block). This is the basis of the Queckenstedt test, mentioned in Chap. 2. In the case of a spinal block, pressure on the abdominal wall, which affects the spinal veins below the point of subarachnoid block, will still increase the lumbar CSF pressure. The Valsalva maneuver—as well as coughing, sneezing, and straining—also causes an increased intrathoracic pressure, which is transmitted to the jugular and then to the cerebral and spinal veins. The ICP rises in heart failure, when central and jugular venous pressures become elevated. Mediastinal tumors, by obstructing the superior vena cava, have the same effect. These increases are manifest despite the presence of valves in the jugular veins. When the heart stops, the CSF pressure falls to zero.

DISRUPTIONS OF CEREBROSPINAL FLUID PRESSURE, VOLUME, AND CIRCULATION

Increased Intracranial Pressure

Physiologic Considerations The intact cranium and vertebral canal, together with the relatively inelastic dura, form a rigid container, such that an increase of any of its contents—brain, blood, or CSF—will elevate the ICP. Furthermore, an increase in volume of any one of these three components must be at the expense of the other two, a relationship that is known as the Monroe-Kellie doctrine. Small increments in brain volume do not immediately raise the ICP because of the countersizing buffering effect of displacement of CSF from the cranial cavity into the spinal canal. To a lesser extent there is deformation of the brain and limited stretching of the infoldings of the relatively unyielding dura, specifically, the falx cerebri between the hemispheres and the tentorium between the hemispheres and cerebellum. Once these compensating measures have been exhausted, a mass within one dural compartment leads to displacement, or “herniation of brain,” from that compartment into an adjacent one. Any further increment in brain volume necessarily reduces the volume of intracranial blood contained in the veins and dural sinuses. Also, the CSF is formed more slowly in circumstances of raised ICP. These accommodative volume-pressure relationships occur concurrently and are subsumed under the term intracranial compliance (the change in ICP for a given change in intracranial volume). As the brain, blood, or CSF volumes continue to increase, the accommodative mechanisms fail and ICP rises exponentially, as in the idealized compliance curve. The normal compliance curve begins its steep ascent at an ICP of approximately 25 mmHg. After this point, small increases in intracranial volume result in marked elevations in ICP.

The numerical difference between ICP and mean blood pressure within the cerebral vessels is termed cerebral perfusion pressure (CPP). Besides the aforementioned brain tissue shifts, which are discussed more fully in relation to their clinical signs in Chap. 17, elevation in ICP that approaches the level of mean systemic blood pressure eventually causes a widespread reduction in cerebral blood flow/perfusion. In its most severe form, this global ischemia produces brain death. Lesser degrees of raised ICP and reduced cerebral circulation cause correspondingly less severe, but still extensive, cerebral infarction of a type quite similar to what arises after cardiac arrest. In all circumstances, not only the severity but also the duration of reduction of CPP are the main determinant of the degree of cerebral damage.

Lundberg is credited with recording and analyzing intraventricular pressures over long periods of time in patients with brain tumors. He found ICP to be subject to periodic spontaneous fluctuations, of which he described three types of pressure waves designated as A, B, and C. Only the A waves have proved to be separable from arterial and respiratory pulsations and of clinical consequence. They consist of rhythmic rises of ICP, up to 50 mmHg, occurring every 15 to 30 min and lasting about 1 min, or of smaller but more protracted elevations. These plateau waves, as they have come to be known, coincide with an increase in intracranial blood volume, presumably as a result of a temporary failure of cerebrovascular autoregulation. Rosner and Becker have observed that plateau waves are sometimes preceded by a brief period of mild systemic hypotension. In their view, this slight hy-
Clinical Features of Raised ICP

Potential causes of raised ICP include:

1. A cerebral or extracerebral mass such as a brain tumor, massive infarction with edema, extensive traumatic contusion, parenchymal, subdural, or extradural hematoma; or abscess, all of which tend to be localized and deform the adjacent brain. The brain deformation is greatest locally, being compartmentalized to a varying degree by dural partitions as already noted.

2. Generalized brain swelling, as occurs in ischemic-anoxic states, acute hepatic failure, hypertensive encephalopathy, hypercarbia, and the Reye hepatocerebral syndrome. Here the increase in pressure reduces the cerebral perfusion pressure, but tissue shifts are minimal because the mass effect is widely distributed throughout the cranial contents.

3. An increase in venous pressure due to cerebral venous sinus thrombosis, heart failure, or obstruction of the superior mediastinal or jugular veins.

4. Obstruction to the flow and absorption of CSF. If the obstruction is within the ventricles or in the subarachnoid space at the base of the brain, hydrocephalus results. Extensive meningeal disease from any number of causes (infectious, carcinomatous, granulomatous, hemorrhagic) is another mechanism. If the block is confined to the absorptive sites adjacent to the cerebral convexities and superior sagittal sinus, the ventricles remain normal in size or enlarge only slightly, because the pressure over the convexities approximates the pressure within the lateral ventricles (see further on).

5. Any process that expands the volume of CSF (meningitis, subarachnoid hemorrhage) or, less commonly, increases CSF production (choroid plexus tumor).

Clinical Features of Raised ICP

The clinical manifestations of increased ICP in children and adults are headache, nausea and vomiting, drowsiness, ocular palsies, and papilledema. After several days or longer, papilledema may result in periodic visual obscurations. If papilledema is protracted, optic atrophy and blindness may follow (see Chap. 13 for further discussion). The practice of monitoring ICP with a pressure device inserted within the cranial cavity has permitted approximate correlations to be made between clinical signs and the levels of ICP. However, it should be kept in mind that the main neurologic signs of a large intracranial mass (pupillary dilatation, abducens palsies, drowsiness, and the Cushing response, as discussed in Chap. 17) are due to displacement of brain tissue and therefore do not bear a strict relationship to ICP. As a rule, patients with normal BP retain normal mental alertness with ICP of 25 to 40 mmHg unless there is concurrent shift of brain tissue. Stated another way, coma generally cannot be attributed to elevated ICP alone. Only when ICP exceeds 40 to 50 mmHg do cerebral perfusion pressure (CPP) and cerebral blood flow diminish to a degree that results in loss of consciousness. Any further elevations are followed intermittently by global ischemia and brain death. Nonetheless, high levels of ICP that are often found under conditions of brain distortion, as discussed in Chaps. 17 and 35, in the context of head injury.

From our own observations, it appears that the brain shift and herniation that causes the pupil to dilate on the side of a mass lesion generally corresponds to an ICP of 28 to 34 mmHg. (Again, this is an association, not a direct effect of the elevated ICP.) However, there are many exceptions, as, for example, when the mass in the medial temporal lobe is contiguous to the third nerve, and with slowly growing lesions, which may raise the ICP with few clinical signs. Likewise, unilateral or bilateral abducens palsies do not bear a strict relationship to the degree of elevation of ICP. This sign is more frequent when raised ICP is due to diffusely distributed brain swelling, hydrocephalus, meningeal processes, or pseudotumor states.

The consequences of increased intracranial pressure differ in infants and small children, whose cranial sutures have not closed. Then the clinical problem involves differentiation from other types of enlargement of the head with or without hydrocephalus, such as constitutional macrocrania or an enlarged brain (megencephaly); or hereditary metabolic diseases such as Krabbe disease, Alexander disease, Tay-Sachs disease, Canavan spongy degeneration of the brain, and from subdural hematoma or hygroma, neonatal ventricular hemorrhage, and various cysts and tumors.

Monitoring of ICP

There is considerable evidence that the outcome in patients with intracranial mass lesions is favorably influenced by maintaining the intracranial pressure at levels well below those which compromise cerebral perfusions. An ICP below 20 mmHg is given as a target, since the compliance curve becomes steep beyond this level and small increments in cerebral volume may cause large elevations in pressure. Unfortunately, the direct measurement of ICP and aggressive measures to counteract high pressures have not yielded uniformly beneficial results, and—after several decades of popularity—the routine use of such devices remains controversial. The problem may be partly a matter of the time at which monitoring is instituted and the proper selection of patients for aggressive treatment of raised ICP. Only if the ICP measurements are to be used as a guide to medical and surgical therapy is their use justified. Also figuring in the decision to institute monitoring are the prospects of ameliorating the underlying lesion, the patient’s age, and the associated medical disease(s). Our practice has been to measure ICP with an indwelling fiberoptic monitor or intraventricular drain in otherwise salvageable patients who are stuporous or comatose and in whom a traumatic or other intracranial mass has caused either a shift of intracranial structures or severe generalized brain swelling. The monitor is generally placed on the same side as a mass lesion.
The emergency management of raised ICP is considered in greater detail in Chaps. 34 and 35, where it is discussed in relation to stroke and cerebral trauma. A comprehensive discussion can also be found in the monograph on intensive care (Ropper) listed in the references.

**Obstructive (Tension) Hydrocephalus**

Essentially, this is a condition in which there is ventricular enlargement under tension as a result of an obstruction to the flow of CSF at some point in its ventricular pathway or aqueduct of Sylvius, at the medullary foramen of exit (Luschka and Magendie), or in the basal subarachnoid space. Because of the obstruction, CSF accumulates within the ventricles under increasing pressure, enlarging the ventricles and expanding the hemispheres. As stated above, in the infant or young child, the head increases in size because the expanding cerebral hemispheres separate the sutures of the cranial bones.

Regarding terminology, it should be noted that the term hydrocephalus (literally, “water brain”) is frequently but incorrectly applied to any enlargement of the ventricles even if consequent to cerebral atrophy, i.e., hydrocephalus ex vacuo, or to ventricular enlargement due to failure of development of the brain, a state known as colpencephaly. Reference to these conditions as hydrocephalic is so common that it is unlikely to change; hence the authors believe it preferable to use the term tension hydrocephalus for the obstructive types in which the CSF is or has been under increased pressure.

In 1914, Dandy and Blackfan introduced the also somewhat inaccurate but now well-established terms communicating and non-communicating (obstructive) hydrocephalus. The concept of a communicating hydrocephalus was based on the observations that dye injected into a lateral ventricle would diffuse readily downward into the lumbar subarachnoid space and that air injected into the lumbar subarachnoid space would pass into the ventricular system; in other words, the ventricles were in communication with the spinal subarachnoid space. If the lumbar spinal fluid remained colorless after the injection of dye, the hydrocephalus was assumed to be obstructive or noncommunicating. In actuality, the distinction between these two types is not fundamental, because all forms of tension hydrocephalus are obstructive at some level, and the obstruction is virtually never complete. Acute and complete aqueductal occlusion is said to be incompatible with survival for more than a few days. The authors suggest that a more appropriate terminology is one in which the site of the presumed obstruction is indicated, e.g., meningeal, aqueductal, or third ventricular tension hydrocephalus.

**Pathogenesis of Obstructive Hydrocephalus**

There are several sites of predilection of obstruction to the flow of CSF. One foramen of Monro may be blocked by a tumor or by horizontal displacement of central brain structures by a large unilateral mass. This causes expansion of one lateral ventricle or a portion of it. Large tumors of the third ventricle (e.g., colloid cyst) may block both foramina of Monro, leading to dilation of both lateral ventricles. The aqueduct of Sylvius, normally narrow to begin with, may be occluded by a number of developmental or acquired lesions with periaqueductal gliosis (genetically determined atresia or forking, ependymitis, hemorrhage, tumor), and lead to dilation of the third and both lateral ventricles. In the hereditary cases reported by Bickers and Adams, the transmission was in three generations of males. If the obstruction was in the fourth ventricle, the dilation included the aqueduct. Other sites of obstruction of the CSF in the ventricular pathways are at the foramina of Luschka and Magendie (e.g., congenital failure of opening of the foramina—Dandy-Walker syndrome). More common is a blockage to flow of CSF in the subarachnoid space around the brainstem due to inflammatory or hemorrhagic fibrosing meningitis. The latter forms of obstruction result in enlargement of the entire ventricular system, including the fourth ventricle. A still useful adage, attributed to Ayer, is that the ventricle closest to the obstruction enlarges the most; meaning, for example, that occlusion of the basal CSF pathways causes a disproportionate enlargement of the fourth ventricle, and a mass within the fourth ventricle leads to a greater dilatation of the third than of the lateral ventricles.

Another potential obstruction site is in the subarachnoid spaces over the cerebral convexities. A matter of considerable practical as well as theoretical interest is whether a meningeal obstruction over the convexities of the cerebral hemispheres, at the site of the arachnoidal villi, or a blockage of the venous sinuses into which the CSF is absorbed, can result in hydrocephalus. Russell, in her extensive neuropathologic material and her review of the world’s literature, could not find a single well-documented example of either of these suggested etiologies, and the same is true of the pathologic material collected by our colleague RD Adams. Moreover, experiments in animals in which all the draining veins had been occluded, a tension hydrocephalus with enlarging lateral ventricles was produced in only a few cases. Yet Gilles and Davidson have stated that tension hydrocephalus in children may be due to a congenital absence or deficient number of arachnoidal villi, and Rosman and Shands have reported an instance that they attributed to increased intracranial venous pressure. Our hesitation in accepting such examples stems from the difficulty that the pathologist has in judging the patency of the basilar subarachnoid space. This is much more reliably visualized by radiologic than by neuropathologic means. Theoretically, as mentioned earlier, if the obstruction is high, near (or in) the superior sagittal sinus, the CSF should accumulate under pressure outside as well as inside the brain, and the ventricles should not enlarge at all or only slightly, and only after a prolonged period.

The rarely encountered radiologic picture of enlarged subarachnoid spaces over and between the cerebral hemispheres coupled with modest enlargement of the lateral ventricles has been referred to as an external hydrocephalus. Although such a condition does exist, many of the cases so designated have proved to be examples of sporadic or familial subdural hygromas or arachnoid cysts.

Processes such as subarachnoid hemorrhage and cerebral hemorrhage or brain abscess that rupture into the ventricles and rapidly expand the volume of CSF produce the most dramatic forms of acute hydrocephalus. The obstruction of the CSF pathways will usually be found within the ventricular system or at the basal meninges. The corresponding clinical syndrome of acute hydrocephalus is described below.

An increase in the rate of formation or decrease in the rate of absorption would be expected to cause an accumulation of CSF and increased ICP. The only reported examples of overproduction of CSF are papillomas of the choroid plexus, but even in this circumstance there is usually an associated ventricular obstruction, either of the third or fourth ventricle or of one lateral ventricle.
Characteristically in these cases, there is both a generalized dilatation of the ventricular system and basal cisterns (possibly due to increased CSF volume) and an asymmetrical enlargement of the lateral ventricles due to obstruction of one foramen of Monro.

**Clinical Picture of Chronic Hydrocephalus** This varies with the age of the patient and chronicity of the condition. Four main clinical syndromes are recognized—one that occurs very early in life and causes enlargement of the head (overt tension hydrocephalus) and another in which the hydrocephalus becomes symptomatic after the cranial sutures have fused and the head remains normal in size (occult hydrocephalus). A special form of the latter is arrested or compensated hydrocephalus of late adult life (normal-pressure hydrocephalus). The fourth type is acute hydrocephalus.

*Overt Congenital or Infantile Hydrocephalus* The cranial bones fuse by the end of the third year; for the head to enlarge, the tension hydrocephalus must develop before this time. It may begin in utero but usually happens in the first few months of life. Even up to 5 years of age (and very rarely beyond this time), a marked increase of ICP, particularly if it evolves rapidly, may separate the newly formed sutures (diastasis). Tension hydrocephalus, even of mild degree, also molds the shape of the skull in early life, and in radiographs the inner table is unevenly thinned, an appearance referred to as “beaten silver” or as convolutional or digital markings. The frontal regions are unusually prominent (bossed) and the skull tends to be brachiocephalic except in the Dandy-Walker syndrome, where, because of bossing of the occiput from enlargement of the posterior fossa, the head is dolichocephalic. With marked enlargement of the skull, the face looks relatively small and pinched and the skin over the cranial bones is tight and thin, revealing prominent distended veins.

The usual causes of this disorder are (1) intraventricular matrix hemorrhages in premature infants, (2) fetal and neonatal infections, (3) type II Chiari malformation, (4) aqueductal atresia and stenosis, and (5) the Dandy-Walker syndrome.

In this type of hydrocephalus, the head usually enlarges rapidly and soon surpasses the 97th percentile. The anterior and posterior fontanels are tense even when the patient is in the upright position. The infant is fretful, feeds poorly, and may vomit frequently. With continued enlargement of the brain, torpor sets in and the infant appears languid, uninterested in his surroundings, and unable to sustain activity. Later it is noticed that the upper eyelids are retracted and the eyes tend to turn down; there is paralysis of upward gaze, and the sclerae above the irises are visible. This is the “setting-sun sign” and has been incorrectly attributed to downward pressure of the frontal lobes on the roofs of the orbits. The fact that it disappears on shunting the lateral and third ventricles indicates that it is due to hydrocephalic pressure on the mesencephalic tegmentum. Gradually the infant adopts a posture of flexed arms and flexed or extended legs. Signs of corticospinal tract damage are usually elicitable. Movements are feeble and sometimes the arms are tremulous. There is no papilledema, but later the optic discs become pale and vision is reduced. If the hydrocephalus becomes arrested, the infant or child is retarded but often surprisingly verbal. The head may be so large that the child cannot hold it up and must remain in bed. If the head is only moderately enlarged, the child may be able to sit but not stand or stand but not walk. If ambulatory, the child is clumsy. Acute exacerbations of hydrocephalus or an intercurrent febrile illness may cause vomiting, stupor, or coma.

The special features of congenital hydrocephalus associated with the Chiari malformation, aqueductal atresia and stenosis, and the Dandy-Walker syndrome are discussed in Chap. 38.

*Occult Tension Hydrocephalus* Here the hydrocephalus becomes evident only after the cranial sutures have closed (Fig. 30-2). The causes of obstruction to the flow of CSF are diverse, and although some are clearly congenital, symptoms may be delayed as late as adolescence or early adult life or even later. In some instances the condition gives rise to a normal-pressure hydrocephalus, as discussed below and in Chap. 7. The clinical features of occult hydrocephalus and the course of the illness are quite variable. Some instances of arrested hydrocephalus are truly occult in that the disease is unrecognized during life or is discovered only by chance imaging of the brain or on postmortem examination. In other cases, the symptoms are intermittent and relatively mild; in still others, they are slowly or rapidly progressive, in the latter instance giving the clinical impression of a subacute disease.

The patient may complain of bifrontal or bioccipital headaches, but often these are not present. Other symptoms and signs are predominantly those of a frontal lobe disorder of mentation or of gait. Slowness of mental response (abulia), inattentiveness, distractibility, perseveration, and inability to plan activity or to sustain any type of complex cognitive function are characteristic. The immediate responses to verbal and other stimuli are normal, though memory may be slightly impaired. Conspicuous by their absence are apraxia, agnosia, or aphasia. Gait deteriorates early in the course of hydrocephalus; such deterioration may be present for years before other symptoms become manifest. The features of gait deterioration are hard to characterize, but the main aspects are discussed below, under “Normal-Pressure Hydrocephalus.” We have seen a few cases in adults in which the gait disturbance appeared abruptly.
enough to give the impression of a cerebellar stroke. A suck reflex and grasp reflexes of the hands and feet are variably present; plantar reflexes are sometimes extensor. Last, there may be sphincteric incontinence, often without the patient’s awareness.

Occult hydrocephalus due to tumor growth is discussed in Chap. 31.

Clinical Picture of Acute Hydrocephalus Surprisingly little has been written about this syndrome despite its frequency in clinical practice. It is seen most often following subarachnoid hemorrhage from a ruptured aneurysm, less often with bleeding from an arteriovenous malformation or from deep hemispheric hemorrhage that dissects into the ventricles; it may also occur as the result of obstruction of the CSF pathways in the fourth ventricle by a tumor or cerebellar-brainstem hemorrhage or within the basal cisterns by neoplastic infiltration of the meninges, although this last process tends to evolve more subacutely. The patient complains of a headache of varying severity and often of visual obscuration, may vomit, and then becomes drowsy or stuporous over a period of minutes or hours. Bilateral Babinski signs are the rule, and in the advanced stages, which are associated with coma, there is increased tone in the lower limbs and extensor posturing. Early in the process, the pupils are normal in size and the eyes may rove horizontally; as the ventricles continue to enlarge, the pupils become miotic, the eyes then cease roving and assume an orthotopic position, or there may be bilateral abducens palsies and limitation of upward gaze. The speed with which hydrocephalus develops determines whether there is accompanying papilledema. If this condition is left untreated, the pupils eventually dilate symmetrically, the eyes no longer respond to oculocephalic maneuvers, and the limbs become flaccid. Rarely, there is an unanticipated cardiac arrest, even at an early stage of evolution of the hydrocephalus; this complication is seen particularly in children and may be presaged by brain compression at the level of the perimesencephalic cisterns, detectable by imaging studies.

Treatment is by drainage of CSF, usually effected by a ventricular catheter or, if there is undoubted communication between all the CSF compartments, by lumbar puncture. The latter may pose some risk if spinal fluid is withdrawn rapidly, thereby creating a pressure gradient between the cerebral and spinal regions.

Neuropathologic Effects of Tension Hydrocephalus Ventricular expansion tends to be maximal in the frontal horns, explaining the hydrocephalic impairment of frontal lobe functions and of basal ganglionic–frontal motor activity in all forms of hydrocephalus. The central white matter yields to pressure, while the cortical gray matter, thalamus, basal ganglia, and brainstem structures remain relatively unaffected. There is an increase in the content of interstitial fluid in the tissue adjacent to the lateral ventricles, readily detected by magnetic resonance imaging (MRI) (Fig. 30-2). Myelinated fibers and axons are injured, but not to the extent that one might expect from the degree of compression; minor degrees of astrocytic gliosis and loss of oligodendrocytes in the affected tissue are present to a decreasing extent away from the ventricles and represent a hydrocephalic atrophy of the brain. The ventricles are characteristically denuded of ependyma and the choroid plexuses are flattened and fibrotic. The lumens of cerebral capillaries in biopsy preparations are said to be narrowed—a finding that is difficult to evaluate.

Normal-Pressure Hydrocephalus (See also pages 105 to 106)

In nonprogressive meningeal and ependymal diseases, hydrocephalus may develop and reach a stable stage. It is said to be “compensated,” in the sense that formation of CSF equilibrates with absorption. The formation of CSF diminishes slightly, perhaps because of compression of the choroid plexuses; absorption increases in proportion to CSF pressure. Once equilibrium is attained, the ICP gradually falls, though it still maintains a slightly higher gradient from ventricle to basal cistern to cerebral subarachnoid space. A stage is reached where the CSF pressure reaches a high normal level of 150 to 200 mmH₂O while the patient still manifests the cerebral effects of the hydrocephalic state. The name given to this condition by Hakim, Adams and Fisher was normal-pressure hydrocephalus (NPH).

A triad of clinical findings is characteristic of NPH—a slowly progressive gait disorder is usually the earliest feature, followed by impairment of mental function, and sphincteric incontinence. Grasp reflexes in the feet and falling attacks may also occur but there are no Babinski signs. Headaches are infrequently a complaint, and there is no papilledema.

The gait disturbance may be of several different types, as discussed in Chap. 7; some of them are difficult to classify, but certain features predominate. Most often it takes the form of unsteadiness and impairment of balance, with the greatest difficulty being encountered on stairs and curbs (Fisher). Weakness and tiredness of the legs are also frequent complaints, although examination discloses no paresis or ataxia. The gait in NPH may convey an impression of Parkinson disease, with short steps and stooped, forward-leaning posture, but there is no rigidity, slowness of alternating movement, or tremor. Other patients present with unexplained falls, often helplessly backward, but on casual inspection the gait may betray no abnormality at all. When the condition remains untreated, the steps become shorter, with frequent shuffling and falls; eventually standing and sitting and even turning over in bed become impossible. Fisher refers to this advanced state as “hydrocephalic astasia-abasia.”

The mental changes in the cases we have encountered have been, broadly speaking, “frontal” in character and embody mainly apathy, dullness in thinking and actions, and slight inattention. Memory trouble is usually a component of the overall problem and has been predominant in some cases, for which reason the diagnosis of Alzheimer disease has been made. There is usually a degree of affective indifference but the patient reports little in the way of emotionality. The extensive study of 63 patients by De Moul largely corroborated these impressions but also found difficulties in verbal, graphical, and calculation skills with which we have not been impressed. It is notable that his patients with verbal difficulties did not improve with shunting, suggesting to us that they had a degenerative dementia. Unfortunately, beyond the above-noted defects that are elicitable by routine testing, we have not found neuropsychologic tests of great value in the diagnosis of NPH. Urinary symptoms appear relatively late in the illness. Initially, they consist of urgency and frequency. Later, the urgency is associated with incontinence, and ultimately there is “frontal lobe incontinence,” in which the patient is indifferent to his lapses of continence.

This syndrome of NPH may follow subarachnoid hemorrhage from ruptured aneurysm or head trauma, a resolved acute meningitis or a chronic meningitis (tubercular, syphilitic, or other), Paget...
disease of the base of the skull, mucopolysaccharidosis of the meninges, and achondroplasia. However, in most cases, the cause cannot be established; presumably it is due to an asymptomatic fibrosing meningitis. That the mechanical effect of ventricular enlargement on the adjacent brain is responsible for the syndrome is supported by Fisher’s observations that a reduction in ventricular size caused even by extrinsic compression from subdural collections is associated with clinical improvement.

Verification of the diagnosis of NPH and the selection of patients for ventriculoatrial or ventriculoperitoneal shunt has presented difficulties. A lumbar puncture should be performed for diagnostic purposes and the pressure measured carefully. As mentioned, the large ventricles, even at a normal pressure, continue to exert a force against the tracts in the cerebral white matter. In most cases of NPH, the CSF pressure is above 155 mmH2O, but the disorder has occurred infrequently with lower pressures, in a few instances as low as 130 mmH2O or even less. The CT scan, as shown in Fig. 30-3 (enlarged ventricles without convolutional atrophy), radionuclide cisternography (reflux into ventricles and delayed pericerebral diffusion), and particularly the clinical response to the removal of CSF have been the most helpful ancillary examinations in our experience (see below). However, the findings are not always clear-cut, and several small series suggest that a negative test does not preclude benefit from shunting (see, for example, Walchenbach et al). Moreover, in these same series, improvement after removal of CSF has had a high predictive value for success with shunting. The span of the frontal horns of the lateral ventricles by CT scanning has also been used as a rough guide to the likelihood of success from ventricular shunting (see below). More relevant is a disproportionate enlargement of the ventricular system in comparison to the degree of cortical atrophy judged by the CT and MRI appearance. Various unwieldy formulas have been designed to assess this ratio. Some guidelines relating the ventricular span to the outcome of treatment are given below. MRI may show some degree of transependymal egress of water surrounding the ventricles, but this is not always the case, and this sign is sometimes difficult to differentiate from the periventricular white matter change that is ubiquitous in the elderly.

Monitoring of CSF pressure over a prolonged period may show intermittent rises of pressure, possibly corresponding to the A waves of Lundberg, but this is not practical in most cases. According to Katzman and Hussey, the infusion of normal saline into the lumbar subarachnoid space at a rate of 0.76 mL/min for 30 to 60 min provokes a rise in pressure (300 to 600 mmH2O) that is not observed in normal individuals. Theoretically, this test should quantitate the adequacy of CSF absorption, but it too has yielded unpredictable results. Whether derivatives of these infusion and pressure trend monitoring tests are valuable is doubtful in our view.

Drainage of large amounts of CSF (20 to 30 mL or more) by lumbar puncture often results in clinical improvement in stance and gait for a few days, although this change is usually not evident for many hours or more after the spinal tap. As mentioned, objective improvement in gait after spinal drainage is one practical way to select patients for shunt operations when the clinical picture is not entirely clear but the test is by no means infallible. When there has been doubt as to the effects of lumbar puncture we have admitted the patient to the hospital and inserted a lumbar drain for 3 days, draining approximately 50 mL of CSF daily and observing the response in gait and mentation. It is worthwhile to quantify the speed and facility of gait two or three times before the lumbar

![Figure 30-3. CT scan of a patient with normal-pressure hydrocephalus. There is enlargement of all the ventricles, particularly of the frontal horns of the lateral ventricles (left), which is roughly disproportionate to the cortical atrophy (right). Various formulas have been devised to quantitate this disporportion, but they are difficult to apply and they are only variably accurate.](image-url)
puncture or drainage and to perform this testing at periodic intervals for several days after the procedure in order to be certain that improvement is genuine. Even more persuasive is a definite improvement followed days later by worsening of gait.

As a group, patients who have a sustained response to drainage of CSF by shunting, as described below, have had the first two elements of the clinical triad (only half of our successfully treated patients have been incontinent), and their lateral ventricular span at the level of the anterior horns was in excess of 50 mm (a true dimension calculated from CT scans), equivalent to approximately 18 mm on the usual CT film, and at the same time, relatively little cerebral atrophy.

**Treatment of Hydrocephalus in Adults**

The development of ventricular shunt tubing with one-way valves opened the way to successful treatment of hydrocephalus. The valve can be set at a desired opening pressure, allowing the CSF to escape directly into the bloodstream (ventriculoatrial shunt), peritoneal cavity (ventriculoperitoneal shunt), or pleural space whenever the pressure level is exceeded. Gratifying success can be obtained, often a complete or nearly complete restoration of mental function and gait, by the placement of such shunts.

Regarding NPH, the most consistent improvement has been attained in that minority of patients in whom a cause could be established (subarachnoid hemorrhage, chronic meningitis, or tumor of the third ventricle). As already noted, other predictors of success are considerable enlargement of the ventricles in comparison to the degree of cortical atrophy, CSF pressures above 155 mmH₂O, and improvement after spinal puncture, but none of these is entirely dependable. Deviations from the characteristic syndrome—such as the occurrence of dementia without gait disorder or the presence of apraxias, aphasias, and other focal cerebral signs—should lead one to a diagnosis other than NPH. Fisher, on analyzing successfully shunted cases, noted that almost without exception gait disturbance was an early and prominent symptom. Uncertainties of diagnosis increase with advancing age owing to the frequent association of degenerative dementia and vascular lesions. However, in Fisher’s experience, age alone does not exclude the existence of NPH as a cause of gait disorder, and long duration of symptoms does not preclude a salutary outcome from shunting. In patients who are averse to the shunting procedure or who have medical conditions that make the surgery inadvisable, it is sometimes possible to produce a reasonable improvement in gait for several months by repeating the spinal puncture and drainage of large amounts of fluid every few weeks or months.

The potential failure of shunting must be anticipated in patients who do not conform to the typical syndrome or whose disease has advanced to the stage of long-standing incontinence or dementia. In some instances, a lack of improvement is explained by inadequate decompression, which justifies a revision of the shunt with a valve that drains at lower pressures. Overdrainage, in contrast, causes headaches that may be chronic or orthostatic and may be associated with small subdural collections of fluid. These fluid collections, or hygromas, consisting of CSF and proteinaceous fluid derived from blood products, are generally innocuous and do not require drainage unless they enlarge or cause focal neurologic symptoms or, rarely, seizures. Some surgeons prefer to insert an externally programmable valve that allows adjustments if the ventricles do not reduce in size or if the opposite, overdrainage, occurs.

Although shunting is relatively simple as a surgical procedure, it is associated with complications, the main ones being postoperative subdural hygroma or hematoma (even at times, if the ventricular pressure is reduced gradually, the bridging dural veins may stretch and rupture); infection of the valve and catheter, sometimes with ventriculitis and occasionally bacteremia; occlusion of the tip of the catheter in the ventricle; and, particularly in infants and children, the “slit ventricle syndrome” (see below). Orthostatic headaches can be overcome by raising the opening pressure of the shunt valve and, if the headaches persist, by utilizing an externally programmable valve. Misplacement of the catheter may rarely transect tracts in the deep hemispheric white matter and cause serious neurologic deficits. It is our impression that this occurs more often when the catheter is inserted from the back rather than through the frontal or parietal regions. The incidence of blockage may be reduced by placing the catheter in the anterior horn of the right ventricle, where there is no choroid plexus. Meticulous aseptic technique and the preoperative and postoperative administration of antibiotics have apparently reduced the incidence of shunt infections.

Most shunts in adults are brought to termination in the peritoneum (ventriculoperitoneal shunt). Rare complications of ventriculoatrial shunting are pulmonary hypertension and pulmonary embolism and nephritis, which is due to low-level infection of the shunt tube with *Staphylococcus*. Puncture of the floor of the fourth ventricle by endoscopic techniques (“third ventriculostomy”) has been explored as an alternative to shunting, but, for a number of reasons, it has not attained popularity among surgeons.

Once the CSF is shunted, the ventricles diminish in size within 3 or 4 days even when the hydrocephalus has been present for a year or more. This indicates that hydrocephalic compression of the cerebrum is largely reversible. Indeed, in Black’s series, the ventricles failed to return to normal in only 1 of his 11 shunted patients, and in that patient there was no clinical improvement. Clinical improvement occurs within a few weeks, the gait disturbance being slower to reverse than the mental disorder. Symptoms of cerebral atrophy due to Alzheimer disease and related conditions are not altered by shunting, but this approach has been periodically resurrected, as discussed by Silverberg.

**Treatment of Infantile and Childhood Hydrocephalus**

Here one encounters more difficulties than in the treatment of the adult disorder. The ventricular catheter may wander or become obstructed and require revision. Peritoneal pseudocysts may form (most shunts in children are ventriculoperitoneal). Another unexpected complication of shunting has been collapse of the ventricles, the so-called slit ventricle syndrome (the appearance of the ventricles on imaging studies is slit-like). This occurs more frequently in young children, though we have observed it in adults. These patients develop a low-pressure syndrome with severe generalized headaches, often with nausea and vomiting, whenever they sit up or stand. Some children become ataxic, irritable, or obtunded or may vomit repeatedly. The CSF pressure is extremely low and the volume of CSF much reduced. In babies, the cranium may fail to grow even though the brain is of normal size. In most shunted patients, the ICP in the upright position is diminished to $-30$ mmH₂O; but in patients with the low-pressure shunt syndrome, it may reach $-100$ to $-150$ mmH₂O. To correct the condition, one would imagine that replacing the shunt valve with another that opens under a higher pressure would suffice. Indeed, this may be successful. But once the condition is established, the most effective measure has been the placement of an antisiphon device, which prevents valve flow when the patient stands. (See further on for a discussion of intracranial hypotension in adults.)
Whether to shunt all hydrocephalic infants soon after birth is a controversial issue. In several large series of cases that have been treated in this way, the number surviving with normal mental function has been small (see review of Leech and Brumback). The series of Dennis and associates is representative. They examined 78 shunted hydrocephalic children and found that 56 (72 percent) had full-scale IQs between 70 and 100; in 22 patients, the IQ was between 100 and 115; in 3 patients, it was below 70, and in 3 others, it was above 115. Mental functions improved unevenly and performance scores lagged behind verbal ones at all levels. The use of the carbonic anhydrase inhibitor acetazolamide or other diuretics to inhibit CSF formation has not been successful in the hands of our colleagues, but several authors believe that by giving 250 to 500 mg of acetazolamide orally daily, shunting can be avoided in both adult normal-pressure and infantile hydrocephalus (Aimard et al; Shinnar et al).

### Increased Intracranial Pressure Due to Venous Obstruction

Occlusion of the major dural venous sinuses (superior longitudinal and lateral) results in increased ICP. This is not surprising in view of the direct effect of venous obstruction on CSF pressure. One such form, due to lateral sinus thrombosis, was referred to by Symonds as “otic hydrocephalus”—a name that he later conceded was inappropriate insofar as the ventricles are not enlarged in this circumstance. As indicated earlier, venous congestion that complicates heart failure and superior mediastinal obstruction also raise the CSF pressure, again without enlargement of the ventricles. This may happen as well with large, high-flow arteriovenous malformations of the brain. The effects of cerebral venous occlusion are considered further in the discussion of pseudotumor cerebri (below) and in Chap. 34.

### Pseudotumor Cerebri

The term pseudotumor cerebri was coined by Nonne in 1914 and has remained a useful means of designating a common and highly characteristic syndrome of headache, papilledema (unilateral or bilateral), minimal or absent focal neurologic signs, and normal CSF composition, all occurring in the absence of enlarged ventricles or an intracranial mass on CT scanning or MRI. Being a syndrome and not a disease, pseudotumor cerebri has a number of causes or pathogenetic associations (Table 30-1). Actually, the most common form of the syndrome has no firmly established cause—i.e., it is idiopathic and is now generally referred to as benign or idiopathic intracranial hypertension.

### Idiopathic Intracranial Hypertension

This syndrome was first described in 1897 by Quincke, who called it “serous meningitis.” It is particularly frequent in overweight adolescent girls and young women, attaining an incidence of 19 to 21 per 100,000 in this group, as compared with 1 to 2 per 100,000 in the general population (Radhakrishnan et al). Increased ICP develops over a period of weeks or months. Relatively unremitting but fluctuating headache, described as dull or a feeling of pressure, is the cardinal symptom; it can be mainly occipital, generalized, or somewhat asymmetrical. Other less frequent complaints are blurred vision, a vague dizziness, minimal horizontal diplopia, transient visual obstructions that often coincide with the peak intensity of the headache, or a trifling numbness of the face on one side. Rarely, the presenting feature may be a nasal CSF leak, as pointed out by Clarke and colleagues. Self-audible bruits have been reported by some of our patients; this has been attributed to turbulence created by differences in pressure between the cranial and jugular veins. The patient is then discovered to have flagrant papilledema (Figs. 13-8 and 13-9), immediately raising the specter of a brain tumor (rarely, papilledema is only minimally developed or absent). The risk of visual loss and the severity of headache in many instances make the term benign intracranial hypertension less acceptable.

The CSF pressure is found to be elevated, usually in the range of 250 to 450 mmHg, but it is not clear whether the brain itself is swollen or, as is more likely, the increased pressure is due entirely to a change in the pressure within the CSF and venous compartments. When the CSF pressure is monitored for many hours, there are fluctuations taking the form of irregularly occurring plateau waves of increased pressure lasting 20 to 30 min and then falling abruptly nearly to normal (Johnston and Paterson).

Aside from papilledema, there is remarkably little to be found on neurologic examination—perhaps a slight unilateral or bilateral abducens palsy, fine uninterpretable nystagmus on far lateral gaze,
or a minor sensory change. Visual field testing usually shows slight peripheral constriction with enlargement of the blind spots. As vision diminishes, more severe constriction of the fields, with greater nasal or inferior nasal loss, is found. Exceptionally, particularly in children, an otherwise typical Bell’s palsy may be associated (Chutorian et al). Mentation and alertness are preserved, and the patient seems surprisingly well aside from the headaches, which infrequently becomes severe enough to limit daily activity. Examinations by CT and MRI have shown the ventricles to be normal in size or small. The sella may be enlarged and filled with CSF ("empty sella," page 577). There is no MRI evidence of change in the water density of the brain.

As remarked above, most of the patients are overweight young women, often with menstrual irregularities, but the condition also occurs in children or adolescents, in whom there is no clear sex predominance, and in men (Digre and Corbett). We have had experience with several familial instances—e.g., affecting mother and daughter. Practically all of the women with this disease are obese and so are the men, but to a lesser degree (Durcan et al). In obese women without the pseudotumor syndrome, CSF pressure usually does not differ from that of normal persons (Corbett and Mehta). All forms of endocrine and menstrual abnormalities (particularly amenorrhea) as well as the use of oral contraceptives have been postulated as causative factors, but none has been substantiated.

Pathophysiology The mechanism of increased CSF pressure in the above-described idiopathic form of the disorder has remained elusive, but recent experience is converging on the possibility that there is a functional obstruction to outflow in the venous sinuses. Karahalios and colleagues and others have found the cerebral venous pressure to be consistently elevated in pseudotumor cerebri; in half of their patients, there was a venous outflow obstruction demonstrated by venography, often with a pressure gradient across the site. These authors proposed that venous hypertension increases the resistance to CSF absorption and is the proximate mechanism underlying pseudotumor. Similarly, Farb and colleagues, using sophisticated MRI venography, visualized venous stenosis in 27 of 29 patients with pseudotumor (and in 4 of 59 control subjects). In both the aforementioned studies and others like them, the nature of the obstruction was not clear, but the fact that in some series it was bilateral and focal suggests that the stenosis was not simply the passive result of raised intracranial pressure. This issue is not yet resolved, as noted below.

A related finding in some cases, pointed out to us some time ago by Fishman, is one of partial obstruction of the lateral sinuses by enlarged pacchionian granulations (seen during the venous phase of conventional angiography). It is here that recent evidence has been most provocative. The intervention by stenting of a venous sinus at the sites of apparent obstruction has resulted in clinical improvement and a reduction in CSF pressure. For example, 5 of 12 patients treated by Higgins and colleagues became asymptomatic, but this was a population selected by the demonstration of a focal gradient in the lateral sinus during venography. Karahalios had similar success in several patients. What is not clear is how prevalent these partial venous obstructions are and what precisely is their nature (if not simply enlarged granulations). In some series, the latter abnormality has been found in 10 to 25 percent of patients who lack any features of pseudotumor (Leach et al).

In an attempt to settle the issue of the venous stenosis as being a secondary effect of raised intracranial pressure, King and colleagues have measured intracranial venous pressure while withdrawing spinal fluid from the cervical subarachnoid space in patients with idiopathic pseudotumor cerebri. Their observation that the venous pressure drops immediately upon the reduction in CSF pressure supports the notion that the increased venous pressure is secondary (furthermore, they describe patients with normal venous pressures in the sagittal and transverse sinuses). The unsatisfactory nature of all the currently offered theories of causation of pseudotumor cerebri are reviewed extensively by Walker; but at the moment, our reading of the literature suggests that venous stenosis, from granulations or from some yet undefined functional change, does account for a large proportion of what had previously been considered to be idiopathic. However, this mechanism does not apply in all cases. How the venous changes relate to obesity and gender is also unclear. Perhaps some individuals have a congenital configuration of the venous sinuses that is exaggerated with obesity of elevated systemic venous pressures.

Some additional comments about the physiologic changes in CSF flow and pressure in relation to alternative mechanisms of pseudotumor may be informative. Using the method of constant infusion manometrics, Mann and coworkers demonstrated an increased resistance to CSF outflow, due to their view to an impaired absorptive function of the arachnoid villi. Other authors have attributed intracranial venous hypertension to raised intra-abdominal and cardiac filling pressures, the mechanical result of obesity (Sugerman et al). Others, on inconclusive evidence, have attributed benign intracranial hypertension to an increase in brain volume secondary to an excess of extracellular fluid or blood volume within the cranium (Sahs and Joynt, Raichle et al). An interesting related finding has been an elevated level of vasopressin in the CSF but not in the blood (Sekel and Lightman). In the goat, this peptide causes a rise in ICP and a reduction in CSF absorption. This raises the possibility that the pseudotumor state is due to an aberration of the transit of water in the cerebrum. Finally, Jacobson and colleagues have made the provocative observation that serum vitamin A levels (in the form of retinol) are 50 percent higher than expected, on average, in patients with pseudotumor—a difference that is not explained by obesity. Because the levels were considerably lower than in cases of hypervitaminosis A with pseudotumor (see below), the meaning of these findings is uncertain.

Symptomatic Causes of Pseudotumor Cerebri (Table 30-1) The main considerations in cases of generalized elevation of ICP and papilledema in the absence of an intracerebral mass are covert occlusion of the dural venous sinuses, gliomatosis cerebri, occult arteriovenous malformation, and carcinomatous, infectious, or granulomatous meningitis. Although occlusion of the dural venous sinuses and their large draining veins is sometimes equated with pseudotumor, these cases are not, strictly speaking, idiopathic. When papilledema occurs in the context of a persistent headache, particularly if the pain is centered near the vertex or medial parietal areas or if there are seizures, venous occlusion is likely. Venous sinus thrombosis can be detected in most instances by careful attention to the appearance of the superior sagittal and lateral sinuses on the T1-weighted MRI or on the contrast-enhanced CT scans, as discussed in Chap. 34 (page 734). Isolated cortical vein thrombosis on the cerebral convexity does not cause pseudotumor.

A large cerebral arteriovenous malformation (AVM), by causing an increase both of venous pressure and cerebral blood volume, can also give rise to a pseudotumor syndrome. In a few of our cases, these changes in the physiology of the cerebral circulation were made evident by the appearance of early venous flow on the angiogram or by thrombosis of the superior sagittal sinus.
Several diseases that are associated with raised CSF protein concentration have given rise to a pseudotumor syndrome, the more common ones being the Guillain-Barré syndrome, systemic lupus, and spinal tumors, particularly oligodendroglioma. Elevated spinal fluid pressure has been attributed to a blockage of CSF absorption by the proteinaceous fluid, but this mechanism has never been validated and fails to explain those few instances in which the Guillain-Barré and pseudotumor syndromes have been associated with a near normal protein content of the CSF. This explanation is even less compelling if one recalls that the protein concentration of the fluid in the cerebral spaces is considerably lower than in the spinal ones. Also, as we have pointed out, when calculated correctly, neither the resistance to CSF absorption nor the colloid osmotic effect attributable to an increased protein content in the spinal fluid is adequate to explain the pressure elevation (Ropper and Marmarou). The mechanism of this type of pseudotumor syndrome is presently unknown.

In addition to mechanical factors, a number of toxic and metabolic disturbances may give rise to a pseudotumor syndrome. In children, as chronic corticosteroid therapy is withdrawn, there may be a period of headache, papilledema, and elevated ICP with little or no enlargement of the lateral ventricles. Lead toxicity in children may be marked by brain swelling and papilledema. Excessive doses of tetracycline and vitamin A (particularly in the form of isoretinoin, an oral vitamin A derivative used in the treatment of severe acne) have also been shown to cause intracranial hypertension in children and adolescents. Ingestion of large quantities of animal (bear) liver is another curious source of intoxication with vitamin A underlying pseudotumor. Isolated instances of hypo- or hyperadrenalism, myxedema, and hypoparathyroidism have been associated with increased CSF pressure and papilledema, and occasionally the administration of estrogens, phenothiazines, the antiarrhythmic drug amiodarone, and quinolone antibiotics has the same effect, for reasons not known.

The first step in differential diagnosis is to exclude an underlying tumor or the nontumorous causes of raised ICP, mainly dural venous occlusion and meningeal inflammation. This can be accomplished by CT and MRI, although it should be borne in mind that certain chronic meningeal reactions (e.g., those due to sarcoidosis or to tuberculous or carcinomatous meningitis), which give rise to headache and papilledema, may sometimes elude detection by these imaging procedures. In these cases, however, lumbar puncture will disclose the diagnosis. It should not need to be emphasized that the diagnosis of idiopathic pseudotumor cerebri should not be accepted when the CSF content is abnormal.

**Visual Loss in Pseudotumor** Careful evaluations of the visual fields and of acuity is required soon after the diagnosis of idiopathic pseudotumor is established. Repeated examination of visual function, preferably in collaboration with an ophthalmologist, is essential in detecting early and potentially reversible visual loss. However, it must be acknowledged that measurements of visual acuity (and of confrontation fields and visual evoked potentials) are relatively insensitive means of detecting early visual field loss and that abnormalities in these tests indicate that serious damage to the optic nerve head has already occurred. Quantitative perimetry, using the kinetic Goldmann technique, has been more informative. The neurologist caring for a patient with pseudotumor is probably best advised to measure visual acuity serially in the office and refer the patient for computed perimetry as an adjunctive test. Fundus photographs are also a reliable means of assessing the course of papilledema. A reduction in previously normal acuity to less than 20/100, an enlargement of the blind spot, or the appearance of sector field defects is an indication for prompt and aggressive treatment.

If intracranial hypertension and papilledema are left untreated or fail to respond to the measures outlined above, there is danger of permanent visual loss from compressive damage to the optic nerve fibers and compression of the central retinal veins. Corbett and associates, who described a group of 57 patients followed for 5 to 41 years, found severe visual impairment in 14, and Wall and George, using highly refined perimetric methods, have reported an even higher incidence of visual loss. Moreover, children with pseudotumor share the same visual risks as adults (Lessell and Rosman). Sometimes vision is lost abruptly, either without warning or following one or more episodes of monocular or binocular visual obscurations.

**Treatment** Most patients with idiopathic intracranial hypertension will be found initially to have minor visual changes aside from the papilledema; the headache and lumbar puncture pressure then guide treatment. Besides symptomatic relief of headaches, the progression of visual loss mentioned above is the main concern. At least one-quarter of our patients have recovered within 6 months after only repeated lumbar punctures and drainage of sufficient CSF to maintain the pressure at normal or near-normal levels (less than 200 mmHgO). The lumbar punctures were performed daily or on alternate days at first and then at longer intervals, according to the level of pressure. Evidently this was sufficient to restore the balance between CSF formation and absorption for at least several months. At the same time, weight loss has been encouraged and the best results have been reported when this was successful.

**Weight Reduction** This is always advised but is difficult to accomplish. In two pathologically obese patients, we have resorted to surgical gastric plication, which had a beneficial effect on the pseudotumor but left the patient for a time with the severe gastrointestinal disturbances that commonly complicate this procedure. Sugerman et al (1999) studied 24 morbidly obese women who had similar operations and found the results to be satisfactory over several years. Two of our patients developed a sensory polyneuropathy after surgery. The use of gastric plication and related procedures is currently undergoing re-evaluation for obesity in general; but in the dire circumstances of pseudotumor with visual loss, it is probably a reasonable alternative.

**Lumbar-Peritoneal Shunting** In patients who are unresponsive to the usual therapeutic measures, one treatment method that may be considered is a lumbar-peritoneal shunt. Only a few of our patients have undergone this surgical procedure. It has been relatively safe and effective, but because of a tendency for the shunt to become obstructed or to be dislodged in obese patients, sometimes causing back or sciatic pain, the procedure has fallen out of favor. Burgett et al, who treated 30 patients in this way, reported success in reducing headache in almost all and in improving vision in 70 percent. Despite its shortcomings, this procedure may be preferable to the optic nerve fenestration described below. We have not had to resort to cranial subtemporal decompression, a procedure that was formerly used when vision was threatened.

**Corticosteroids** Prednisone (40 to 60 mg/day), oral hyperosmotic agents such as glycerol (15 to 60 mg four to six times daily), or carbonic anhydrase inhibitors (acetazolamide 500 mg twice or thrice daily; furosemide 20 to 80 mg twice daily) to reduce CSF formation all have their advocates. We have occasionally observed a gradual recession of papilledema and a lowering of CSF pressure
in response to each of these measures, but such responses were not consistent or sustained and it was always difficult to decide whether they represented the effect of treatment or the natural course of the disease. Greer, who has reported on 110 patients, 11 of whom were treated with these agents, decided that they were of no value. Moreover, in patients whose papilledema seems to recede under the influence of corticosteroids, there is always a danger that it will recur when the drug is tapered. Considering the potential for undesirable side effects of corticosteroids, we have used them very sparingly and only for brief periods while preparing the patient for more definitive treatment. Many authorities eschew their use entirely and objected strenuously to their relative endorsement in previous editions of this book.

**Fenestration of the Optic Nerve Sheath** For patients who are progressively or rapidly losing vision, a procedure that was in past years favored by some ophthalmologists is unilateral fenestration of the optic nerve sheath. According to Corbett and colleagues, this procedure—which consists of partial unroofing of the orbit and intraorbital incision of the dural-arachnoid sheaths surrounding the optic nerve—effectively preserved or restored vision in 80 to 90 percent of patients. Even when this procedure is performed on only one side, its effect on vision is often bilateral, and about two-thirds of patients have some relief of headache as well, albeit this has been transient in most of our patients.

However, the operation carries a moderately high risk of vascular obstruction and unilateral visual loss, as happened in two of our patients. The causes of visual loss after this operation are mainly vascular and have included central retinal artery or vein occlusion, choroidal infarction, optic nerve trauma, hemorrhage into the nerve sheath, and infection. Over the past decade, enthusiasm for the procedure has diminished after reports of several series where there was visual loss in 2 to 11 percent of patients. Some of these data come from studies of sheath fenestration for ischemic optic neuropathy, a condition not comparable to the disc swelling of pseudotumor. Perhaps more compelling are follow-up studies indicating that the reduction in intracranial pressure was limited to a year or less. As a result of recent re-examination of the complications of this procedure, most of our colleagues recommend a lumboperitoneal shunt as the first approach, even while acknowledging that half such shunts become occluded or displaced over time and then require replacement.

In a large number of patients, the CSF pressure remains elevated and the papilledema becomes chronic (Fig. 13-10). It is the management of this group that is most difficult and controversial.

At the moment, the clinician is left with little clear direction as to the course of treatment of pseudotumor cerebri. In cases with no visual impairment and with tolerable headaches, we favor aggressive weight reduction and repeated lumbar punctures. For more severe cases, we have advised lumbar drainage to the peritoneum and administration of acetazolamide, or if vision is threatened, optic sheath fenestration by an experienced surgeon. We have also been impressed with the persistence of a complex migraine- or tension-like headache in some patients whose CSF pressure has been adequately reduced by repeated lumbar punctures, shunting, or optic nerve fenestration. After it has been confirmed that the pressure is not elevated, these headaches may be treated in a manner similar to the usual types of chronic headaches, as outlined in Chap. 10. Therapeutic lumbar puncture in pseudotumor may be followed transiently by the type of low-pressure headache described further on; it generally does not warrant treatment in these circumstances.

**Pneumocephalus and Pneumocranium** These disorders, in which air enters the ventricular system or the subarachnoid spaces, are discussed in relation to cranial injury and the postoperative state (page 749 and Fig. 35-3). In the case of pneumocranium, the collection of air may act as a mass that compresses adjacent brain tissue and requires relief by aspiration.

**Ventricular Dilatation without Raised Pressure or Brain Atrophy** The wide application of CT and MRI reveals cases of lateral and third ventricular enlargement in which there is no evidence of parenchymal lesions of the cerebrum. Usually it is slight in degree and represents hydrocephalus ex vacuo. This has been reported in patients with anorexia nervosa and Cushino disease and in those receiving corticosteroids for a long period of time. It has also been observed in children with protein malnutrition and in some schizophrenics and chronic alcoholics. In all of the aforementioned conditions, slight widening of the cerebral sulci accompanies the ventricular enlargement. In alcoholic patients, there is usually no associated irreversible neurologic or mental abnormality. After a prolonged period without steroids or of abstinence from alcohol, the ventricles tend to become smaller and the sulcal widening is less apparent. This change in ventricular size is probably related to a shift of brain tissue fluids.

**Intracranial Hypotension**

**Lumbar Puncture Headache** (See also page 159) This is a well-known phenomenon, attributable to a lowering of ICP by leakage of CSF through the needle track into the paravertebral muscles and other tissues. Once begun, the headache may last for days or, rarely, even weeks. Most characteristic is the relation of the headache to upright posture and its relief within moments after assuming the recumbent position. Actually, the syndrome includes more than headache. There may be pain at the base of the skull posteriorly and in the back of the neck and upper thoracic spine, stiffness of the neck, and nausea and vomiting. At times the signs of meningal irritation are so prominent as to raise the question of postlumbar puncture meningitis, although lack of fever usually excludes this possibility. In addition to a low or unmeasurable CSF pressure if another spinal tap is performed (the CSF pressure is found to be in the range of 0 to 60 mmHg), there are occasionally a few to a dozen white cells in the CSF, which may further raise concern of meningitis. In the infant or young child, stiffness of the neck may be accompanied by irritability, unwillingness to move, and refusal of food. If the headache is protracted, recency still reduces it, but a feeling of dull pressure may remain, which the patient continues to report as pain. Many patients also report that shaking the head produces a cephalic pain. Occasionally there will be a sixth nerve palsy or a self-audible bruit from turbulence in the intracranial venous system.

It has been recognized that low CSF pressure is associated on the MRI with prominent dural enhancement by gadolinium (Fig. 30-4)—and, when the syndrome is protracted and severe, there may be small subdural effusions (see below, under “Spontaneous Intracranial Hypotension”).

The use of a 22- to 24-gauge needle and the performance of a single clean (atraumatic) tap seemingly reduces the likelihood of a post—lumbar puncture headache, as discussed in Chap. 2. A period of enforced recumbency, though widely practiced as a means of preventing headache, probably does not lessen its incidence (Carbaat and van Crevel). The ingestion of large volumes of fluids
Spontaneous Intracranial Hypotension

This is a less well known syndrome, in which the same problem of low pressure as that which follows lumbar puncture occurs after straining, a non-hurtful fall, or for no known reason. The cardinal feature is orthostatic headache and only rarely are there other neurologic complaints such as diplopia from sixth nerve palsy or a self-audible bruit. In these cases the CSF pressure is low (60 mmH₂O or less) or not measurable; the fluid may contain a few mononuclear cells but is most often normal. A few cases have presented with stupor as a result of downward transtentorial displacement of the diencephalic region (Pleasure et al) or an upper cervical myelopathy caused by downward deformation and displacement of the spinal cord (Miyazaki et al).

In many such patients, there has been a tear in the delicate arachnoid surrounding a nerve root, with continuous leakage of CSF. The site of the leak is difficult to ascertain except when it occurs into the paranasal sinuses (CSF rhinorrhea). In a series of 11 patients with spontaneous intracranial hypotension, a putative leak was found by radionuclide cisternography or CT myelography (the preferred procedure) in the cervical region or at the cervicothoracic junction in 5 patients, in the thoracic region in 5, and the lumbar region in 1 (Schievink et al). In the patients who underwent surgical repair, a leaking meningeal diverticulum (a so-called Tarlov cyst) was found and could be ligated. This seems to be the most common cause. A blood patch, as described above, may also be useful and should be attempted before resorting to surgery. Recumbency for a few days thereafter permits the pressure to build up, and there has been no recurrence in the cases that we have encountered. Others, however, have reported repeated episodes of orthostatic headache.

As noted above, a helpful diagnostic sign is prominent dural enhancement with gadolinium on the MRI (Fig. 30-4), a phenomenon attributed by Fishman and Dillon to dural venous dilatation; this finding may extend to the pachymeninges of the posterior fossa and the cervical spine. According to Mokri and colleagues, biopsy of the dura and underlying meninges in these cases shows fibroblastic proliferation and neovascularity with an amorphous subdural fluid. There may be subdural effusions and mass effect, either on the cerebral convexities, temporal lobes, optic chiasm, or cerebellar tonsils. Using ultrasound, Chen and colleagues have also described an enlarged superior ophthalmic vein and increased blood flow velocity in this vessel, both of which normalize after successful treatment. Rarely, a case of intracranial hypotension becomes chronic; the headache is then no longer responsive to recumbency. Mokri and colleagues have also made the point that orthostatic headache and diffuse pachymeningeal enhancement on MRI may occur in the presence of normal CSF pressures; observation of these characteristic features should prompt a search for the site of CSF leakage despite the normal pressure.

The use in hydrocephalus of a one-way shunt valve may be complicated by a syndrome of low CSF pressure. Reference has already been made to this syndrome and to the slit ventricles in children who have been treated for hydrocephalus. Usually the valve setting is too low, and readjustment to maintain a higher pressure is corrective.

Also appropriate to mention here are CSF leaks that occur...
after cranial, nasal, or spinal surgery. These give rise to some of the most intractable low-pressure syndromes and must be investigated by radiologic and nuclear studies in order to establish the site of leakage. Several such leaks in our experience have been intermittent, adding to the difficulty in diagnosis.

SPECIAL MENINGEAL AND EPENDYMAL DISORDERS

The effects of bacterial invasion of the pia-arachnoid, cerebrospinal subarachnoid space, ventricles, and ependyma are described in Chap. 32 and summarized in Table 32-1. The point being made here is that these structures may also be involved in a number of noninfective processes, some of obscure origin.

Since the ventricular and subarachnoid spaces are in continuity, one would expect that a noxious agent entering any one part would extend throughout the CSF pathway. Such is not always the case. The lower spinal roots or spinal cord alone may be implicated in “spinal arachnoiditis.” A similar process may affect the optic nerves and chiasm exclusively (“opticochiasmatic arachnoiditis,” see below). This may be accompanied by a pachymeningitis, and the latter may also be restricted to the cervical dura, also discussed below. A predominant localization to these basal or cervical structures may be apparent even in cases of diffuse cerebrospinal meningeal reactions, perhaps because of an uneven concentration of the noxious agent. In other instances, the primary disease appears to have arisen in the dura, with extension only to the adjacent pia-arachnoid. In yet other instances, the ependyma of the aqueduct or fourth ventricle is primarily involved.

The mechanisms by which these meningeal reactions affect parenchymal structures (brain, cord, and nerve roots) are not fully understood. The most obvious sequela is an obstruction to the flow of CSF in hydrocephalus; here, simple fibrotic narrowing of the CSF circulatory pathway is causative. Progressive constriction of nerve roots and spinal cord, literally a strangulation of these structures, is another plausible mechanism, but it is difficult to separate vascular factors from mechanical ones. Since any toxic agent introduced into the subarachnoid space has free access, via Virchow-Robin spaces, to the superficial parts of the brain and spinal cord, direct parenchymal injury may follow. Perivascular reactions of subpial vessels, as in infectious processes, would be a plausible mechanism of injury to optic nerves and spinal cord, where long stretches of myelinated fibers abut the pia.

Regional Arachnoiditis Arachnoiditis limited to the lumbo-sacral roots has followed ruptured discs, myelograms, and spinal surgery. Usually, there is sciatica and chronic neuropathic pain in the back and lower extremities, but sensorimotor and reflex changes in the legs are variable. The MRI shows irregularly enhancing roots and arachnoidal thickening; myelography discloses loculated pockets of imaging media (Fig. 11-6). This condition is discussed further in Chap. 11, under “The Failed-Back Syndrome.”

Another form of spinal arachnoiditis, in which both the spinal cord and roots are entrapped in thickened pia-arachnoid, sometimes with arachnoid-dural adhesions, is rare but well-known entity. An account of this condition is included with the spinal cord diseases (see Chap. 44). The etiologic factors have been singularly elusive although in the past it followed the instillation of iophendylate (Pantopaque) for myelography and corticosteroids (for pain or multiple sclerosis) and other irritative agents. The condition may be accompanied by cranial basal meningeal fibrosis with optic nerve involvement and hydrocephalus (see below), or it may occur in isolation. The most familiar form of spinal arachnoiditis was, in the past, that which followed the use of chemically contaminated spinal anesthetics. Our colleagues saw more than 40 cases of this type, now rare, dating from the time when vials of anesthetic were stored in detergent sterilizing solutions. Instillation of the anesthetic agent was followed immediately by back pain and a rapidly progressive lumbosacral root syndrome (areflexic paralysis, anesthesia of the legs, and paralysis of sphincters). Several cases have, in our recent experience, followed prolonged spinal anesthesia with the patient in a decubitus position, usually for orthopedic procedures, but the resulting myelopathy or cauda equina radiculopathy is then difficult to separate from a direct toxic effect of the anesthetic. The CSF protein rises rapidly in cases that were precipitated by injection of substances in the subarachnoid space, but pleocytosis is minimal. In other instances, protracted back pain lasting days to weeks is the only effect but is followed, after a period of months or years, by a progressive myelopathy. This takes the form of some combination of spinal arachnoiditis with ataxic paraparesis and sensory disturbance, hydrocephalus, or optico-chiasmatic arachnoiditis. The point to be made is that there is always some risk attached to the subarachnoid instillation of any foreign agent.

Opticochiasmatic Arachnoiditis This condition was well known to neurologists during the period when neurosyphilis was a common disease. It occurs after years of chronic syphilitic meningitis, sometimes in conjunction with tuberculous meningitis. However, there were always nonsyphilitic cases, the cause of which was never ascertained. A constriction of visual fields, usually bilateral and asymmetrical (rarely scotomas), developed insidiously and progressed. Pathologically, the optic nerves were found to be enmeshed in thickened, opaque pia-arachnoid. The optic nerves are atrophic in appearance. Idiopathic cases are likely to be confused with multiple sclerosis.

Pachymeningitis The term pachymeningitis refers to a chronic, circumscribed, inflammatory thickening of the dura. The term is somewhat confusing insofar as the pia and arachnoid are usually equally involved in the inflammatory thickening and all three membranes are bound together by dense fibrous adhesions. This type of meningeal reaction, which is now exceedingly uncommon, was first described by Charcot and Joffroy. It occurred mainly in the cervical region (hence the name pachymeningitis cervicalis hypertrophica) and was attributed to syphilis. Indeed, in some instances there was a gummatous thickening of the dura. Involvement of cervical roots and compression of the spinal cord gave rise to variable degrees of paraparesis in association with root pain, paresthesias, sensory loss, and atrophy of the upper limbs. In the modern era, rheumatoid arthritis, sarcoidosis, and chronic local infection (fungal, tuberculous) have been the main causes, but some of the cases remain unexplained. Idiopathic instances continue to be reported; a summary of published cases and two personally studied ones is given by Dumont and colleagues.

The subdural space and dura can be involved by extension of a pathologic process from the arachnoid, especially in infants and children, in whom subdural hygromas regularly follow meningitis. The fibrous connective tissue of which the dura is composed may also undergo pronounced thickening in the course of a mucopolysaccharidosis, especially in cases where fibroblasts are implicated. The basal pia-arachnoid may be involved, leading to obstructive hydrocephalus. Older medical writings often made reference to syphilitic cranial pachymeningitis, which later proved to be the
thickened membranes of subdural hematomas. The neovascular response and fibrosis of the dura and meninges that result from low CSF pressures and give the same appearance as pachymeningitis on enhanced CT scans and MRI have been discussed earlier in the chapter.

Other Abnormalities of the Ependyma and Meninges

Although the ependyma may be involved as part of any chronic meningeal reaction, it may also be the site of a relatively isolated process. In experimental animals, Johnson and colleagues found that the mumps virus could localize in and destroy ependymal cells. This results in activation of subependymal astrocytes, which may bury the remaining ependymal cells and, by overgrowth, narrow the aqueduct of Sylvius. Ependymitis with similar consequences may be the dominant change in infantile toxoplasmosis and cytomegalic encephalitis. Spinal fluid and meningeal reactions to degradation products released from tumors that are in contact with the cerebrospinal spaces, particularly dermoid and craniopharyngioma, are discussed in Chap. 32.

Hemosiderosis (Superficial Siderosis) of the Meninges

Sometimes mistaken by neuropathologists for hemochromatosis, which has entirely different effects on the nervous system, hemosiderosis is clearly the consequence of repeated contamination of the meninges by blood (McDougal and Adams; Fishman). An oozing vascular malformation or tumor has been the usual cause in our experience, although there have been instances in which the source of the blood could not be found. The red blood corpuscles are phagocytosed, with the formation of hemosiderin, and gradually both iron pigment and ferritin are released into the CSF. As a result, the surface of the cerebellum, spinal cord, hippocampi, and olfactory bulbs are stained orange-brown. Iron pigments and ferritin, which are toxic, gradually diffuse through the pia into superficial parts of the cerebellum, eighth cranial nerve, and spinal cord, destroying nerve cells and exciting a glial reaction. In microscopic sections stained for iron, the histiocyte-microglial cells contain iron and ferritin, and particles of iron can be seen studding nerve and glial cells for a distance of several millimeters beneath the pia.

The clinical syndrome of siderosis of the meninges consists essentially of a progressive ataxia and nerve deafness; sometimes a spastic paraparesis is added and, rarely, mental impairment. The hemosiderin and iron-stained meninges are readily visualized by MRI, since iron is strongly paramagnetic. All the iron-impregnated tissues are hypointense in T2-weighted images. Koepf and associates attributed the vulnerability of the acoustic nerves to their extended meningeal exposure before acquiring a fibroblastic perineurium and epineurium. There is no other treatment than finding the source of the meningeal blood and preventing further hemorrhage and treating hydrocephalus if it is present.

CHAPTER 31

INTRACRANIAL NEOPLASMS
AND PARANEOPLASTIC DISORDERS

Speaking generally, tumors of the central nervous system (CNS) constitute a bleak but vitally important chapter of neurologic medicine. Their importance derives from the facts that they occur in great variety; produce numerous neurologic symptoms because of their size, location, and invasive qualities; usually destroy the tissues in which they are situated and displace those around them; are a frequent cause of increased intracranial pressure; and, most of all, are often lethal. Slowly this dismal state of affairs is changing, as a result of advances in anesthesiology, stereotactic and micro-neurosurgical techniques, radiation therapy, and the use of chemotherapeutic agents.

For clinicians, it should be a matter of general knowledge that:

1. Many types of tumor, both primary and secondary, occur in the cranial cavity and spinal canal. Certain ones are much more frequent than others and are prone to occur in particular age groups.

2. Some tumors—such as craniopharyngioma, meningioma, and schwannoma—have a disposition to grow consistently in particular parts of the cranial cavity, thereby producing highly characteristic neurologic syndromes.

3. The presence of certain diseases such as AIDS, inherited disorders such as neurofibromatosis, or some systemic cancers predisposes to the development of tumors of the nervous system.

4. The growth rates and invasiveness of tumors vary; some, like the glioblastoma, are highly malignant, invasive, and rapidly progressive and others, like the meningioma, are benign, slowly progressive, and compressive. These pathologic peculiarities are important, for they have valuable clinical implications, frequently providing the explanation of slowly or rapidly evolving clinical states and determining a good or poor prognosis.

5. Systemic neoplasms, by poorly understood mechanisms, may have remote effects on the nervous system, quite apart from those due to their compressive, infiltrative, or metastic actions. Moreover, these remote effects, referred to as paraneoplastic, may constitute the initial or only clinical manifestation of the underlying neoplasm.

6. Metastatic neoplasms are a far more common cause than are primary tumors of brain and spinal cord, and certain cancers display this tendency more than others.

Incidence of CNS Tumors and Their Types  Currently, in each year there are an estimated 540,000 deaths from cancer in the United States. Of these, the number of patients who died of primary tumors of the brain seems comparatively small (about 18,000, half of them malignant gliomas), but in roughly another 130,000 patients the brain is affected at the time of death by metastases. Thus, in approximately 25 percent of all the patients with cancer, the brain and its coverings are involved by neoplasm at some time in the course of the illness. By comparison, there are about 200,000 new cases of breast cancer yearly. Among causes of death from intracranial disease, tumor is exceeded in frequency only by stroke. By contrast, in children, primary tumors of the brain constitute the most common solid tumor and represent 22 percent of all childhood neoplasms, second in frequency only to leukemia. Viewed from another perspective, in the United States, the yearly incidence of all tumors that involve the brain is 46 per 100,000, and of primary brain tumors, 15 per 100,000.

It is difficult to obtain accurate statistics as to the types of intracranial tumors, for most of them have been obtained from university hospitals with specialized neurosurgical centers, which attract the more easily diagnosed and treatable forms. For example, from the figures of Posner and Chernik, one can infer that secondary tumors of the brain greatly outnumber primary ones; yet in the large series reported in the past (those of Cushing, Olivcrona, Zülch, and Zimmerman), only 4 to 8 percent were of this type. In the autopsy statistics of municipal hospitals, where one would expect a more natural selection of cases, the figures for metastatic tumors vary widely, from 20 to 42 percent (Russell and Rubinstein). Even these estimates probably err on the low side, since the brain is frequently not examined in cancer patients, and many of the patients with more benign tumors may have found their way to specialized neurosurgical services. With these qualifications, the figures in Table 31-1 might be taken as representative.

In broad terms, most primary brain tumors are of glial-cell origin—i.e., gliomas—a category that includes astrocytomas (which occur in several grades of malignancy), oligodendrogliomas, ependymomas (which may have characteristics of both glia and of epithelium), and a number of rarer types. Other tumors arise from ectodermal structures related to the brain (meningioma); an increasingly important group arises from lymphocytes or their progenitor histiocytes, i.e., reticulum cells (CNS lymphoma); a varied constellation is derived from precursor neuronal elements (neuroblastoma, medulloblastoma), germ cells (germinoma, craniopharyngioma, teratoma, etc.), or endocrine elements (pituitary adenoma). A more recent and detailed tabulation is given in Table 31-2, compiled by the Central Brain Tumor Registry. Notable in all series, and emphasized in the latter table, is the higher frequency of certain tumors during childhood.

The main change since the first edition of this book (1977) is the increase in incidence of primary CNS lymphomas. When Table 31-1 was first composed, the incidence of this tumor, formerly called reticulum-cell sarcoma, was almost negligible. In the last 25 years, the number in our hospitals has more than tripled; in specialized centers such as the Memorial Sloan-Kettering Cancer Center, the increase in incidence has been even more dramatic (DeAngelis). In most institutions, one in five or six primary brain tumors is now of this type. For the most part, this increase is attributable to the rise in number of immunosuppressed individuals, particularly of those with AIDS; but the incidence of this tumor...

*a In children, the proportions differ: astrocytoma, 48 percent; medulloblastoma, 44 percent; ependymoma, 8 percent. Seventy percent of gliomas in children are infratentorial; in adults, 70 percent are supratentorial. Craniopharyngioma also occurs mainly in younger age groups.

*b The incidence of lymphoma was negligible when these series were collected, but it has increased markedly since then (see text).

also appears to be increasing even in those with ostensibly normal immune function.

Classification and Grading of Nervous System Tumors  Classifications and grading systems of intracranial tumors abound and are often confusing to the general neurologist. Most classifications have been based on the presumed cell of origin of the neoplasm, while grading systems are meant to be an estimate of the rate of growth and clinical behavior, but the two are often concordant. The most recent WHO classification represents a current view of tumor specialists but is unfortunately too unwieldy for most clinicians; a discussion of this system can be found in the article by Kleihues and colleagues. In order to make this system comprehensible, what follows is an extracted synopsis of (1) modern refinements in the histopathologic study of gliomas, (2) the numerical grading system of Daumas-Duport and coworkers (also known as the St. Anne–Mayo system), (3) the three-tiered system of Ringertz (which correlates most closely with clinical survival), and (4) the aforementioned new third edition of the World Health Organization’s classification (which incorporates the Ringertz system). These pathologic systems notwithstanding, it is becoming apparent that there are practical consequences to subclassifying tumors by additional molecular methods (see further on).

The astrocytic tumors, the most common forms of glioma, have been subdivided into diffuse well-differentiated astrocytoma (grade II), anaplastic astrocytoma (grade III), and glioblastoma multiforme (grade IV). These represent a spectrum in terms of growth potential (degree of nuclear atypia, cellularity, mitoses, and vascular changes) and prognosis. The glioblastomas, which are largely defined by the added features of necrosis and anaplasia of nonneural elements such as vascular proliferation, are set apart from anaplastic astrocytomas on the basis not only of their histology but also by a later age of onset than astrocytoma and a more rapid course. Tumors formerly classified as grade I astrocytomas are rare and difficult to distinguish from hamartomas; therefore they are currently omitted from most classifications. In the WHO system, grade I is reserved for the relatively benign pilocytic astrocytomas (well-differentiated tumors mostly of children and young adults). Similarly, the pleomorphic xanthoastrocytomas (with lipid-filled cells) and the subependymal giant-cell astrocytomas (usually associated with tuberous sclerosis) have been set apart because of their different growth patterns, pathologic features, and prognosis.

The ependymomas are subdivided into cellular, myxopapillary, clear-cell, and mixed types; the anaplastic ependymoma and the subependymoma are given separate status. The pathologic criteria of malignant astrocytoma do not apply to oligodendroglia,

</table>
for reasons elaborated further on. Tumors derived from the choroid plexus are divided into two classes—papillomas and carcinomas, both rare. Meningiomas are classified on the basis of their cytoarchitecture and genetic origin into four categories: the usual meningothelial or syncytial type, the fibroblastic and angioblastic variants, and the malignant type. Tumors of the pineal gland, which were not included in earlier classifications, comprise germ-cell tumors, the rare pineocytomas, and pineoblastomas. The medulloblastoma has been reclassified with other tumors of presumed neuroectodermal origin, namely neuroblastoma, retinoblastoma, and ependymoblastoma.

Given separate status also are the intracranial midline germ-cell tumors, such as germinoma, teratoma, choriocarcinoma, and endodermal sinus carcinoma. A miscellaneous group comprises large-cell reticular lymphoma (CNS lymphoma), hemangioblastoma, chordoma, hemangiopericytoma, spondioblastoma, and ganglieneuroma.

Tumors of cranial and peripheral nerves are believed to differentiate into three main types: schwannomas, neurofibromas, and neurofibrosarcomas.

**Biology of Nervous System Tumors** In considering the biology of primary nervous system tumors, one of the first problems is with the definition of neoplasia. It is well known that a number of lesions may simulate brain tumors in their clinical manifestations and histologic appearance but are really hamartomas and not true tumors. A hamartoma is a “tumor-like formation that has its basis in maldevelopment” (Russell) and undergoes little change during the life of the host. The difficulty one encounters in distinguishing it from a true neoplasm, whose constituent cells multiply without restraint, is well illustrated by tuberous sclerosis and von Recklinghausen neurofibromatosis, where both hamartomas and neoplasms are found. In a number of mass lesions—such as certain cerebellar astrocytomas, bipolar astrocytomas of the pons and optic nerves, von Hippel-Lindau cerebellar cysts, and pineal teratomas—a clear distinction between neoplasms and hamartomas is often not possible.

The many studies of the *pathogenesis of brain tumors* have gradually shed light on their origin. Johannes Muller (1838), in his atlas *Structure and Function of Neoplasms*, first enunciated the appealing idea that tumors might originate in embryonic cells left in the brain during development. This idea was elaborated by Cohnheim (1878), who postulated that the source of tumors was an anomaly of the embryonic anlage. Ribbert, in 1918, extended this hypothesis by postulating that the potential for differentiation of these stem cells would favor blastomatous growth. This Cohnheim-Ribbert theory seems most applicable to tumors that arise from vestigial tissues, such as craniopharyngiomas, teratomas, lipomas, and chordomas, some of which are more like hamartomas than neoplasms.

For many years, thinking about the pathogenesis of primary CNS tumors was dominated by the *histogenetic theory* of Bailey and Cushing (1926), which is based on the known or assumed embryology of nerve and glial cells. Although it is not a popular notion today, Bailey and Cushing attached the suffix *blastoma* to indicate all tumors composed of primitive-looking cells such as glioblastoma and medulloblastoma. One prominent theory is that most tumors arise from neoplastic transformation of mature adult cells (*dedifferentiation*). A normal astrocyte, oligodendrocyte, microglia, or ependymocyte is transformed into a neoplastic cell and, as it multiplies, the daughter cells become variably anaplastic, the more so as the degree of malignancy increases. (Anaplasia refers to the more primitive undifferentiated state of the constituent cells.) However, it is currently thought that many tumors arise from more primitive elements, specifically stem cells, and it may be that the ostensible dedifferentiation is an artifact of the histologic appearance of tumors.

The factor of age is also important in the biology of brain tumors. Medulloblastomas, polar spongioblastomas, optic nerve gliomas, and pinealomas occur mainly before the age of 20 years, and meningiomas and glioblastomas are most frequent in the sixth decade. Heredity figures importantly in the genesis of certain tumors, particularly retinoblastomas, neurofibromas, and hemangioblastomas. The rare familial disorders of multiple endocrine neoplasia and multiple hamartomas are associated with an increased incidence of anterior pituitary tumors and meningiomas, respectively. Glioblastomas and cerebral astrocytomas have also been reported occasionally in more than one member of a family, but the study of such families has not disclosed the operation of an identifiable genetic factor. Only in the gliomas associated with neurofibromatosis and tuberous sclerosis and in the cerebellar hemangioblastoma of von Hippel-Lindau is there significant evidence of a hereditary determinant.

Although there is no direct evidence for an association between viruses and primary tumors of the nervous system, epidemiologic and experimental data—drawn from studies of the human papillomavirus and the hepatitis B, Epstein-Barr, and human T-lymphotropic viruses—indicate that they may be a risk factor in certain human cancers. In transgenic mice, certain viruses are capable of inducing olfactory neuroblastomas and neurofibromas. Each of these viruses possesses a small number of genes that are incorporated in a cellular component of the nervous system (usually a dividing cell such as an astrocyte, oligodendrocyte, ependymocyte, endothelial cell, or lymphocyte). The virus is believed to thrive on the high levels of nucleotides and amino acid precursors and at the same time acts to force the cell from of its normal reproductive cycle into an unrestrained replicative cycle (Levine). Because of this capacity to transform the cellular genome, the virus product is called an oncogene; such oncogenes are capable of immortalizing, so to speak, the stimulated cell to form a tumor.

**Molecular and Genetic Features of Brain Tumors** All of the above ideas have been expanded greatly by studies of the human genome, which have led to the identification of certain chromosomal aberrations linked to tumors of the nervous system. What has emerged from these studies is the view that the biogenesis and progression of brain tumors are a consequence of defects in the control of the cell cycle. Some molecular defects predispose to tumor genesis; others underlie subsequent progression and accelerated malignant transformation. In effect, this model presupposes the acquisition of multiple defects over time. In some instances, the initial predisposition is a genetic defect that is inherited by germline transmission and that the additional events arise as somatic genetic lesions. For example, mutations in genes that normally suppress cell proliferation may set the stage for tumor development. Typically, these inherited mutations affect only one of two copies of the tumor suppressor or gene. By itself, such a mutation does not cause cancer. However, if the second copy of the gene acquires a mutation (e.g., from a chemical toxin or irradiation), the tumor suppression function of the gene is lost and cancerous transformation of the cell becomes likely. These notions are consistent with the observation that many of the gene defects that predispose to cancer are dominantly inherited.
The above model is well illustrated by consideration of the astrocytoma. Among the first detectable changes are mutations that inactivate the tumor suppressor gene, p53 on chromosome 17p; over 50 percent of astrocytomas have deletions encompassing this gene. Other early changes include overexpression of growth factors or their receptors as noted below. After the tumor develops, progression to a more malignant grade of astrocytoma or to a glioblastoma may be triggered by defects in the p16-retinoblastoma gene signaling pathway, loss of chromosome 10 (seen in about 90 percent of high-grade gliomas), or overexpression of the epidermal growth factor gene. In fact, it is striking that analysis of the patterns of these defects correlates accurately with the staging and aggressive characteristics of these tumors.

Knowledge of the molecular signatures of certain other tumors has immense clinical value. For example, as discussed further on, oligodendroglialomas that have combined deletions in chromosomes 1p and 19q respond well to chemotherapy, and this property may increase survival by more than 10 years. This type of information may spare the nonresponsive patient from ineffective, sometimes toxic therapy (see Reifenberger and Louis; Louis et al).

Much of the modern genetic classification of brain tumors is derived from the technical tour de force of gene microarrays. The patterns of these multiple gene analyses are able to distinguish some types of medulloblastomas from the similar-appearing primitive neuroectodermal tumors; the medulloblastomas express classes of genes that are characteristic of cerebellar granule cells, suggesting they arise from these cells. Also, these gene expression signatures confer useful prognostic information in a more general way than noted above for oligodendroglialoma. For example, medulloblastomas that express genes indicative of cerebellar differentiation are associated with longer survival than those expressing genes related to cell division (Pomeroy et al).

Furthermore, as alluded to earlier, in about 50 percent of gliomas there is an overexpression or a mutant form of epidermal growth factor (EGF) and of transforming growth factor alpha (TGF-α), suggesting a role for these in the progression of certain tumor types. Other trophic factors are overexpressed in yet other brain neoplasms and perhaps contribute to their morphology and growth pattern; for example, VEGF is found in extremely high concentrations in meningiomas, which are highly vascular by nature. These findings, taken together, suggest an autocrine stimulation of growth by these factors and possibly an interaction with some of the aforementioned gene defects. However, having emphasized molecular and chromosomal changes, it is not yet clear if any of them is truly causative (the currently favored hypothesis) or if they simply reflect an aberrant genetic process that accompanies the dedifferentiation of tumor growth and progression.

On the basis of this new molecular information, our views of the pathogenesis of neoplasia are being cast along new lines. Some of the specifics of these new data are presented in the following discussions of particular tumor types. A more extensive review can be found in the article by Osborne and colleagues, including the heterogeneity of findings that suggests polygenic changes in most gliomas.

**Pathophysiology of Brain Tumors**

The production of symptoms by tumor growth is governed by certain principles of mechanics and physiology, some of which were discussed in Chaps. 17 and 30. There it was pointed out that the cranial cavity has a restricted volume, and the three elements contained therein—the brain (about 1200 to 1400 mL), cerebrospinal fluid (CSF; 70 to 140 mL), and blood (150 mL)—are relatively incompressible, particularly the brain substance, and each is subject to displacement by a localized mass lesion. According to the Monro-Kellie doctrine, the total bulk of the three elements is at all times constant, and any increase in the volume of one of them must be at the expense of one or both of the others discussed in Chap. 30. A tumor growing in one part of the brain therefore compresses the surrounding brain tissue and displaces CSF and blood; once the limit of this accommodation is reached, the intracranial pressure (ICP) rises. The elevation of the ICP and periorbital pressure impair axonal transport in the optic nerve and the venous drainage from the optic nerve head and retina, manifesting itself in papilledema.

It must be pointed out, however, that only some brain tumors cause papilledema and that many others—often quite as large—do not. Thus one may question whether the Monro-Kellie doctrine, and its simple implied relationships of intracranial volume and CSF pressure, fully accounts for the development of raised ICP and papilledema with brain tumors. This discrepancy is in part because, in a slow process such as tumor growth, brain tissue is to some degree compressible, as one might suspect from the large indentations of brain produced by massive meningiomas.

Presumably, with tumor growth, the venules in the cerebral tissue adjacent to the tumor are compressed, with resulting elevation of capillary pressure, particularly in the cerebral white matter. The slow growth of most tumors permits accommodation of the brain to changes in cerebral blood flow and ICP. Only in the advanced stages of tumor growth do the compensatory mechanisms fail and CSF pressure and ICP rise, with consequences described in Chap. 30. Once pressure is raised in a particular compartment of the cranium, the tumor begins to displace tissue at first locally and at a distance from the tumor, resulting in a number of false localizing signs including coma, described in Chap. 17. Indeed, the transtentorial herniations, the paradoxical corticospinal signs of Kernohan and Woltman, sixth and third nerve palsies, occipital lobe infarcts, midbrain hemorrhages, and secondary hydrocephalus were all originally described in tumor cases (see further on, under “Brain Displacements and Herniations”).

**Brain Edema**

This is a most important aspect of tumor growth, but it also assumes importance in cerebral trauma, infarction, abscess, hypoxia, and other toxic and metabolic states. Brain edema is such a prominent feature of cerebral neoplasm that this is a suitable place to summarize what is known about it.

For a long time it has been recognized that conditions leading to peripheral edema, such as hypo-albuminemia and increased systemic venous pressure, do not have a similar effect on the brain. By contrast, lesions that alter the blood-brain barrier cause rapid swelling of brain tissue. Klatzo specified two categories of edema, vasoergic and cytotoxic. Fishman adds a third, which he calls interstitial edema. An example of the latter is the edema that occurs with obstructive hydrocephalus, especially when the ependymal lining is lost and CSF seeps into the periventricular tissues in the spaces between cells and myelin. Most neuropathologists use the term interstitial to refer to any increase in the extravascular intercellular compartment of the brain; this would include both vasoergic and Fishman’s interstitial edema.

Vasoergic edema is the type seen in the vicinity of tumor growths and other localized processes as well as in more diffuse injury to the blood vessels (e.g., lead encephalopathy, malignant
Normal, vasogenic, and cytotoxic edema are described in detail. Vasogenic edema is characterized by increased permeability of the capillary endothelial cells, allowing plasma proteins to exude into the extracellular spaces. This heightened permeability is due partly to a defect in the tight endothelial cell junctions but mainly to active vesicular transport across endothelial cells. Microvascular transudative factors, such as proteases released by tumor cells, also contribute to vasogenic edema by weakening the blood-brain barrier and allowing passage of blood proteins. The small protein fragments that are generated by this protease activity exert osmotic effects as they spread through the white matter of the brain. This is the postulated basis of the regional swelling, or localized cerebral edema, that surrounds the tumor. Experimentally, the increase in permeability has been shown to vary inversely with the molecular weight of various markers; for example, inulin (molecular weight 5000) enters the intercellular space more readily than albumin (molecular weight 70,000).

The particular vulnerability of white matter to vasogenic edema is not well understood; probably its loose structural organization offers less resistance to fluid under pressure than the gray matter. Possibly it is also related to special morphologic characteristics of white matter capillaries. The accumulation of plasma filtrate, with its high protein content, in the extracellular spaces and between the layers of myelin sheaths would be expected to alter the ionic balance of nerve fibers, impairing their function, but this has never been demonstrated satisfactorily.

By contrast, in cytotoxic edema, all the cellular elements (neurons, glia, and endothelial cells) imbibe fluid and swell, with a corresponding reduction in the extracellular fluid space. Since a shift of water occurs from the extracellular to the intracellular compartment, there is relatively little mass effect, quite the opposite of what occurs with the vascular leak of vasogenic edema. This cellular edema occurs typically with hypoxic-ischemic injury. The effect of oxygen deprivation is to cause a failure of the ATP-dependent sodium pump within cells; sodium accumulates in the cells, and water follows (Fig. 31-1B). The term cellular edema is preferable to cytotoxic edema because it emphasizes intracellular ionic movement and not the implication of a toxic factor. In pure form, it is most often due to hypoxia, but it may also complicate acute hypo-osmolality of the plasma, as in dilutional hyponatremia, acute hepatic encephalopathy, inappropriate secretion of antidiuretic hormone, or the osmotic disequilibrium syndrome of hemodialysis (page 970). Presumably, both cellular and vasogenic edema occur with cerebral infarction. It is notable that several other common metabolic and nutritional encephalopathies—such as nor-

**Figure 31-1.** A. Schematic representation of the astrocytes and endothelial cells of the capillary wall in the normal state (above) and in vasogenic edema (below). Heightened permeability in vasogenic edema is due partly to a defect in tight endothelial junctions but mainly to active vesicular transport across endothelial cells. B. Cellular (cytotoxic) edema, showing swelling of the endothelial, glial, and neuronal cells at the expense of the extracellular fluid space of the brain. (Reproduced by permission from Fishman.)
motensive uremia and thiamine and vitamin B₁₂ deficiencies—are attended by neither vasogenic nor cytotoxic edema.

So-called interstitial (hydrocephalic) edema as defined by Fishman is a recognizable condition but is probably of less clinical significance than cytotoxic or cellular edema. Pathologically, in tension hydrocephalus, the edema extends for only 2 to 3 mm from the ventricular wall. However, MRI suggests that the periventricular edema is more extensive than what is observed pathologically. Also, there are experimental data to show that a transpendymal or periventricular route is utilized for absorption of CSF in hydrocephalus (Rosenberg et al). We would refer to this state as periventricular interstitial edema in association with tension hydrocephalus.

**Treatment of Brain Edema and Raised ICP** (See also page 766)

The definitive treatment of any given case (excision of a tumor, treatment of intracranial infection, placement of a shunt, etc.) will, of course, be governed by the underlying disease. Here we consider only the therapeutic measures that can be directed against the edema itself and the raised ICP that it causes in cases of brain tumor.

The use of high-potency glucocorticosteroids has a beneficial effect on the vasogenic edema associated with tumors, both primary and metastatic, sometimes beginning within hours. Probably these steroids act directly on the endothelial cells, reducing their permeability. Steroids also shrink normal brain tissue, thus reducing overall intracranial pressure. In addition, drugs such as dexamethasone reduce the vasogenic edema associated with brain abscess and head injury, but their usefulness in cases of large cerebral infarctions, contusions, and hemorrhage is less clear. Possibly the swelling of necrotic tissue is reduced; however, there is no evidence that cytotoxic or cellular edema responds to administration of glucocorticoids.

For patients with brain tumor, it is common practice to use doses of dexamethasone of approximately 4 mg every 6 h, or the equivalent dose of methylprednisolone (Solu-Medrol), while a few patients require a rigid schedule; otherwise, a dose with meals and at bedtime usually suffices to suppress headache and focal tumor signs. In patients with large tumors and marked secondary edema, further benefit is sometimes achieved by the administration of extremely high doses of dexamethasone, to a total of 100 mg per day or more. An initial dose may be given intravenously. Always to be kept in mind are the potentially serious side effects of sustained steroid administration, even at standard dose levels. Therefore the schedule should be carefully titrated to the desired clinical effect. It is also recognized that these drugs interfere with the metabolism of certain anticonvulsants commonly used in brain tumor patients.

In patients who have brain edema and who require intravenous fluids, solutions containing water (“free water”) not matched by equivalent amounts of sodium should be avoided. Normal saline (314 mosmol/L) is preferable and lactated Ringer’s solution (osmolality 289 mosmol/L) is acceptable, but dextrose solutions alone, in any concentration (except D₅/NS), are to be avoided because of their hypo-osmolar nature.

The parenteral administration of hypertonic solutions, to which the brain is only partially permeable (mannitol, hypertonic saline, urea, glycerol), by shifting water from brain to plasma, is an effective means of reducing brain volume and lowering ICP. Edema, however, is actually little affected by these agents. Mannitol is the most widely used; a 25% solution is administered parenterally in a dose of 0.5 to 1.0 g/kg body weight over a period of 2 to 10 min. Hypertonic saline solutions (3 or 1.5%) are equally effective. Urea is used less often and glycerol is not much favored in the United States because of its high caloric content, but it is used in Europe, largely because it can be taken orally on an outpatient basis. A single administration of these solutes has only a short-lived effect, a matter of several hours or less as the brain extracellular space reaches an equilibrium concentration, but repeated use on a regular schedule can lead to a reduction in headache and stabilization of some of the deleterious effects of a mass. Certain diuretic drugs, notably acetazolamide and furosemide, are said to be helpful in special instances (interstitial edema, pseudotumor cerebri) by virtue of creating a hyperosmolar state and by reducing the formation of CSF. However, their effects are usually transient. Aside from a diuresis, which may raise serum osmolality, highly permeable solutes such as glucose do little to reduce brain volume, since they do not create an osmolar gradient that moves water from the brain to the vasculature. Furthermore, with repeated administration of hyperosmolar solutions such as mannitol or with diuretics, the brain gradually increases its osmolality—the result of added intracellular solute; these agents are therefore not suitable for long-term use. The notion that hyperosmolar agents might exaggerate tissue shifts by shrinking normal brain tissue has not been substantiated. The net effect of hyperosmolar therapy is reflected roughly by the degree of hyperosmolarity and hypermamentia that is attained.

Controlled hyperventilation is another method of rapidly reducing brain volume by producing respiratory alkalosis and cerebral vasoconstriction; it is used mainly in brain trauma with high ICP (see Chap. 55), during intracranial surgery, and in the management of patients who have become acutely comatose from the mass effect of a tumor, but its effect is brief.

**Brain Displacements and Herniations** (See also Chap. 17)

The problem of brain displacements and herniations is of vital importance in all mass lesions, and the underlying principles are particularly relevant to enlarging brain tumors. The main aspects of this problem, particularly the coma-producing mechanisms, have been considered on page 310. The pressure from a mass within any one dural compartment causes shifts or herniations of brain tissue to an adjacent compartment where the pressure is lower. The three well-known herniations are: subfalcial, transtentorial, and cerebellar–foramen magnum (see Fig. 17-1), and there are several less familiar ones (upward cerebellar-tentorial, diencephalic–sella turcica, and orbital frontal–middle cranial fossa). Herniation of swollen brain through an opening in the calvarium, in relation to craniocerebral injury or operation, is yet another (transcalvarial) type. As mentioned, the transtentorial herniations relating primarily to coma were discussed in Chap. 17. Here, those that are often seen in cases of brain tumor are emphasized. The writings of Meyer, Jefferson, and Kernohan may be consulted for the early descriptions of the herniations.

Subfalcial herniation, in which the cingulate gyrus is pushed under the falx, occurs frequently, but little is known of its clinical manifestations except that there is often occlusion of an anterior cerebral artery and frontal lobe infarction. The cerebellar–foramen magnum herniation or pressure cone, described by Cushing in 1917, consists of downward displacement of the inferior medial parts of the cerebellar hemispheres (mainly the ventral paraflocculi or tonsillae) through the foramen magnum, behind the cervical cord. The displacement may be bilateral or, in the case of a one-sided cerebellar lesion, ipsilateral. Bilateral displacement may re-
sult from a centrally placed callosal-frontal tumor or from general swelling of the brain and is accompanied by downward displacement of the brainstem. It may also be accompanied by bilateral temporal lobe–tentorial herniations. The clinical manifestations of downward cerebellar herniation are less well delineated than those of the temporal lobe–tentorial herniation. Cushing considered the typical signs of cerebellar herniation to be episodic tonic extension and arching of the neck and back and extension and internal rotation of the limbs, with respiratory disturbances, cardiac irregularity (bradycardia or tachycardia), and loss of consciousness. Other signs with subacutely evolving masses in the posterior fossa include pain in the neck, stiff neck, head tilt, and paresthesias in the shoulders, dysphagia, and loss of tendon reflexes in the arms. It is difficult to determine which signs are due to the cerebellar herniation per se and which to the attendant effects of ICP and hydrocephalus. We would suggest that head tilt, stiff neck, arching of the neck, and paresthesias over the shoulders are attributable to the herniation and that tonic extensor spasms of the limbs and body (so-called cerebellar fits) and coma are due to the compressive effects of the cerebellar lesion on medullary structures or of hydrocephalus on upper brainstem structures. In any case, respiratory arrest is the most feared and often a fatal effect of medullary compression. It may occur suddenly, without the additional aforementioned signs. The herniated parts of the inferior cerebellum may undergo infarct necrosis and swelling, adding to the medullary compression.

With cerebellar mass lesions there may also be upward herniation of the cerebellum through the notch of the tentorium. The clinical effects have not been clearly determined, but Cuneo and colleagues have attributed decerebrate posturing and pupillary changes—initially both pupils are miotic but still reactive, progressing to anisocoria and enlargement—to this type of brain displacement.

An understanding of the effects of elevated intracranial pressure, localized vasogenic edema, and displacements of tissue and herniations are absolutely essential to understanding the clinical behavior of intracranial tumors and mass lesions of any type. Often the symptoms of intracranial tumors are related more to these effects than to invasion or destruction of neurologic structures by the tumor. The several false localizing signs (coma, unilateral or bilateral abducens palsy, pupillary changes, ipsilateral or bilateral corticospinal tract signs, etc.) are also attributable to these mechanical changes and tissue displacements.

**CLINICAL AND PATHOLOGIC CHARACTERISTICS OF BRAIN TUMORS**

It should be stated at the outset that tumors of the brain may exist with hardly any symptoms. Often a slight bewilderment, slowness in comprehension, or loss of capacity for sustained mental activity is the only deviation from normal, and signs of focal cerebral disease are wholly lacking. In some patients, on the other hand, there is early indication of cerebral disease in the form of a progressive hemiparesis, a seizure occurring in a previously well person, or some other dramatic symptom, but until imaging studies are performed, the evidence may not be clear enough to warrant the diagnosis of a cerebral tumor. In a third group, the existence of a brain tumor can be assumed because of the presence of increased intracranial pressure with or without localizing signs of the tumor. In yet another group, the symptoms are so definite as to make it likely that not only is there an intracranial neoplasm but that it is of a certain type and is located in a particular region. These localized growths create certain characteristic syndromes seldom caused by any other disease.

In the further exposition of this subject, intracranial tumors are considered in relation to these common modes of clinical presentation:

1. **Patients who present with focal cerebral signs and general impairment of cerebral function, headaches, or seizures**
2. **Patients who present with evidence of increased intracranial pressure**
3. **Patients who present with specific intracranial tumor syndromes**

**Patients Who Present with General Impairment of Cerebral Function, Headaches, or Seizures**

Until the advent of modern imaging procedures, these were the patients who presented the greatest difficulty in diagnosis and about whom decisions were often made with a great degree of uncertainty. Their initial symptoms are vague, and not until some time has elapsed will signs of focal brain disease appear; when they do, they are not always of accurate localizing value. Altered mental function, headache, dizziness, and seizures are the usual manifestations in this group of patients.

**Changes in Mental Function**

The early symptoms may be subtle. A lack of persistent application to everyday tasks, undue irritability, emotional lability, mental inertia, faulty insight, forgetfulness, reduced range of mental activity (judged by inquiring about the patient’s introspections and manifested in his conversation), indifference to common social practices, lack of initiative and spontaneity—all of which may incorrectly be attributed to anxiety or depression—make up the mental abnormalities seen in this clinical circumstance. Inordinate drowsiness or apathy may be prominent. We have sought a convenient term for this complex of symptoms, which is perhaps the most common type of mental disturbance encountered with neurologic disease, but none seems entirely appropriate. There is both a reduction in the amount of thought and action and a slowing of reaction time. MacCabe refers to this condition as “mental asthenia,” which has the merit of distinguishing it from depression. We prefer to call it *psychomotor asthenia* or general psychomotor derangement. Much of this change in behavior is accepted by the patient with forbearance; if any complaint is made, it is of being weak, tired, or dizzy (nonrotational). Within a few weeks or months, these symptoms become more prominent. When the patient is questioned, a long pause precedes each reply (abulia); at times the patient may not respond at all. Or, at the moment the examiner decides that the patient has not heard the question and prepares to repeat it, an appropriate answer is given, usually in few words. Moreover, the responses are often more intelligible than one would expect, considering the patient’s torpid mental state. There are, in addition, patients who are overtly confused or demented. If the condition remains untreated, dullness and somnolence increase gradually and, finally, as increased intracranial pressure supervenes, the patient progresses to stupor or coma.

Mental symptoms of this type cannot be ascribed to disease in any particular part of the brain, but tumors that cause them are more likely to involve central structures, i.e., they are situated deep in the brain, so as to impair the function of the thalamocortical...
mechanisms underlying attention and alertness, and the long association fiber systems of the cerebral white matter (affecting frontal and temporal areas and the corpus callosum). Probably, these features reflect dysfunction of the frontal lobes, although as often as not, the tumor is in another part of the brain.

**Headaches** (See also page 158) These are an early symptom in fewer than one-quarter of patients with brain tumor and are variable in nature. In some the pain is slight, dull in character, and episodic; in others it is severe and either dull or sharp but also intermittent. If there are any characteristic features of the headache, they would be its nocturnal occurrence or presence on first awakening and perhaps its deep, nonpulsatile quality. However, these are not specific attributes, since migraine and hypertensive vascular headaches may also begin in the early morning hours or on awakening. But if vomiting occurs at the peak of the head pain, tumor is highly likely as noted below. Occipito-nuchal headache with vomiting is indicative of a tumor in or near the cerebellum and foramen magnum.

Tumor patients do not always complain of the pain even when it is present but may betray its existence by placing their hands to their heads and looking distressed. When headache appears in the course of the psychomotor asthenia syndrome, it serves to clarify the diagnosis, but not nearly as much as does the occurrence of a seizure.

The mechanism of the headache is not fully understood. In the majority of instances, the CSF pressure is normal during the first weeks when the headache is present, and one can attribute it only to local swelling of tissues and to distortion of blood vessels in or around the tumor. Later the headache appears to be related to increases in intracranial pressure, thus the early morning occurrence after recumbency and vomiting, as discussed in Chap. 10. Tumors above the tentorium cause headache on the side of the tumor and in its vicinity, in the orbitofrontal, temporal, or parietal region; tumors in the posterior fossa usually cause ipsilateral retroauricular or occipital headache. With elevated intracranial pressure, bifrontal or bioccipital headache is the rule regardless of the location of the tumor.

**Vomiting and Dizziness** Vomiting appears in a relatively small number of patients with a tumor syndrome and usually accompanies the headache when the latter is severe. It is more frequent with tumors of the posterior fossa. The most persistent vomiting (lasting several weeks) that we have observed has been in patients with low brainstem gliomas, fourth ventricular ependymomas, and subependymal gliomas. Some patients may vomit unexpectedly and forcibly, without preceding nausea (projectile vomiting), but others suffer both nausea and severe discomfort. Usually the vomiting is not related to the ingestion of food; often it occurs before breakfast.

No less frequent is the complaint of dizziness. As a rule it is not described with accuracy and consists of an unnatural sensation in the head, coupled with feelings of strangeness and insecurity when the position of the head is altered. Frank positional vertigo may be a symptom of a tumor in the posterior fossa (see Chap. 15).

**Seizures** The occurrence of focal or generalized seizures is the other major manifestation besides slowing of mental functions and signs of focal brain damage. Convulsions have been observed, in various series, in 20 to 50 percent of all patients with cerebral tumors. A first seizure during adulthood is always suggestive of brain tumor and, in the authors’ experience, has been the most common initial manifestation. The localizing significance of seizure patterns has been discussed on pages 275 to 278. Seizures due to brain tumor most often have a focal onset, i.e., are partial and then become generalized. There may be one seizure or many, and they may follow the other symptoms or precede them by weeks or months or—exceptionally, in patients with low-grade astrocytoma, oligodendroglioma, or meningioma—by several years. Status epilepticus as an early event is rare but has occurred in a few of our patients. As a rule the seizures respond to standard anticonvulsant medications and may improve after surgery for tumor removal.

**Regional or Localizing Symptoms and Signs** Sooner or later, in patients with psychomotor asthenia, headaches, and seizures, focal cerebral signs will be discovered; some patients may present with such signs. Nearly always, however, the focal signs are at first slight and subtle. Frequently, CT scanning or MRI will have disclosed the presence of a tumor before either focal cerebral signs or the signs of increased intracranial pressure have become evident.

The cerebral tumors that are most likely to produce the syndromes described above are glioblastoma multiforme, astrocytoma, oligodendroglioma, ependymoma, metastatic carcinoma, meningioma, and primary lymphoma of the brain. The clinical aspects of these diseases, which happen to be the most common brain tumors in adults, are discussed in the sections below.

**Glioblastoma Multiforme and Anaplastic Astrocytoma (High-Grade Gliomas)** These tumors, which constitute the high-grade gliomas, account for about 20 percent of all intracranial tumors, or about 55 percent of all tumors of the glioma group, and for more than 80 percent of gliomas of the cerebral hemispheres in adults. Although predominantly cerebral in location, they may also arise in the brainstem, cerebellum, or spinal cord. The peak incidence is in middle adult life (mean age for the occurrence of glioblastoma is 56 to 60 years and 46 years for anaplastic astrocytoma), but no age group is exempt. The incidence is higher in men (ratio of approximately 1.6:1). Almost all of the high-grade gliomas occur sporadically, without a familial predilection.

The glioblastoma, known since the time of Virchow, was definitively recognized as a glioma by Bailey and Cushing and given a place in their histogenetic classification. Most arise in the deep white matter and quickly infiltrate the brain extensively, sometimes attaining enormous size before attracting medical attention. The tumor may extend to the meningeal surface or the ventricular wall, which probably accounts for the increase in CSF protein (more than 100 mg/dL in many cases) as well as for an occasional pleocytosis of 10 to 100 cells or more, mostly lymphocytes. The CSF may be normal, however. Malignant cells, carried in the CSF, may form distant foci on spinal roots or cause a widespread meningeal gliomatosis. Extraneural metastases, involving bone and lymph nodes, are very rare; usually they occur only after a craniotomy has been performed. About 50 percent of glioblastomas occupy more than one lobe of a hemisphere or are bilateral; between 3 and 6 percent show multicentric foci of growth and thereby simulate metastatic cancer.

The tumor has a variegated appearance, being a mottled gray, red, orange, or brown, depending on the degree of necrosis and presence of hemorrhage, recent or old. The imaging appearance is usually that of a nonhomogeneous mass, often with a center that is hypointense in comparison to adjacent brain and demonstrating an irregular thick or thin ring of enhancement, surrounded by edema.
Part of one lateral ventricle is often distorted, and both lateral and third ventricles may be displaced contralaterally (Fig. 31-2).

The characteristic histologic findings of glioblastoma are great cellularity with pleomorphism of cells and nuclear atypia; identifiable astrocytes with fibrils in combination with primitive forms in many cases; tumor giant cells and cells in mitosis; hyperplasia of endothelial cells of small vessels; and necrosis, hemorrhage, and thrombosis of vessels. This variegated appearance distinguishes glioblastoma from the anaplastic astrocytomas, which show frequent mitoses and atypical cytogenic features but no grossly necrotic or hemorrhagic areas. It is the necrotic and sometimes cystic areas that appear hypointense on imaging studies. The vasculature and fibroblasts undergo a sarcomatous transformation with prominent reticulin and collagen in surrounding tissue. The vascular and connective tissue changes suggest the elaboration of a growth factor by the tumor tissue. Originally, the glioblastoma was thought to be derived from and composed of primitive embryonal cells, but it is now generally thought to arise through anaplasia of maturing astrocytes. It should be emphasized that the histologic grade may vary from site to site within a tumor and it is common for sites of anaplastic astrocytoma and glioblastoma to coexist; in some tumors there are even sites of well-differentiated astrocytoma. It is a fair statement that the most aggressive component (e.g., glioblastic elements) determines the tumor’s behavior. To some extent, this behavior is related to some of the aforementioned genetic changes. Amplification of the epidermal growth factor receptor gene (EGFR) is characteristic of older patients with tumors that begin entirely as glioblastomas, while mutations on the TP53 gene tend to occur in younger individuals whose tumors progress from an astrocytoma to a glioblastoma.

The natural history of untreated glioblastoma is well known. Less than one-fifth of all patients survive for 1 year after the onset of symptoms, and only about 10 percent live beyond 2 years (Shapiro). Age is the most important prognostic factor in this group of tumors; fewer than 10 percent of patients over age 60 survive for 18 months, in comparison to two-thirds of patients under age 40. Survival with anaplastic astrocytoma is somewhat better, typically 3 to 5 years. Cerebral edema and increased intracranial pressure are usually the immediate causes of death. Survival rates with treatment are discussed below.

The diagnosis must usually be confirmed by a stereotactic biopsy or by a craniotomy that aims to remove as much tumor as is feasible at the same time. At operation, only part of the tumor can be removed; its multicentricity and diffusely infiltrative character defy the scalpel. Partial resection of the tumor (“debulking”), however, seems to prolong survival slightly.

Treatment  Except for palliation, little can be done to alter the course of glioblastoma. For a brief period, corticosteroids, usually dexamethasone in doses of 4 to 10 mg every 4 to 6 h, are helpful if there are symptoms of mass effect such as headache or drowsiness; local signs and surrounding edema tend to improve as well. Anticonvulsants are not required unless there have been seizures, but some neurologists and neurosurgeons administer them in order to pre-empt a convulsion. Serious skin reactions (erythema multiforme and Stevens-Johnson syndrome) may occur in patients receiving phenytoin at the same time as cranial radiation (Delattre et al). Usually a maximally feasible resection, the debulking described above, is combined with external beam radiation and chemotherapy. Total cranial irradiation (4500 cGy), boosted with a dose to the region of the tumor (1500 to 2000 cGy), increases survival by
5 months on average (see below). The addition of the chemotherapeutic agent carmustine (BCNU) alone increases survival slightly. Although there are no satisfactory randomized trials, it is considered by most neuro-oncologists that somewhat longer survival can be achieved when a combination of drugs—procarbazine, lomustine (CCNU), and vincristine (a combination termed PCV)—is given (Levin et al). Cisplatin and carboplatin provide similar marginal improvement in survival beyond that obtained by debulking and radiation therapy. In keeping with general experience in this field, the report of the Glioma Meta-analysis Trialists (GMT) Group concluded there was a clear but small benefit of chemotherapy. Brachytherapy (implantation of iodine-125 or iridium-193 beads or needles) and high-dose focused radiation (stereotactic radiosurgery) have so far not significantly altered survival times.

The treatment of recurrent tumor after surgery and radiation, an almost inevitable occurrence, is controversial and must be guided by the location and pattern of tumor growth, the patient’s age, and relative state of health. Almost all glioblastomas recur within 2 cm of their original site and 10 percent develop additional lesions at distant locations. Reoperation is sometimes undertaken for local recurrences, as is brachytherapy, both with uncertain results. The most aggressive approach, a second surgery and chemotherapy, has been generally utilized in patients under age 40 whose original operation was many months earlier. If the PCV regimen discussed above has not already been used, that combination or the newer and better-tolerated alkylating agent temozolomide (which may be used if the PCV regimen was administered previously) are sometimes used in cases of recurrent glioblastoma and anaplastic astrocytoma. In general, these chemotherapeutic drugs prolong the symptom-free interval but have little effect on survival.

With aggressive surgical removal and radiotherapy, as described above, median survival for patients with glioblastoma is 12 months, compared to 7 to 9 months without such treatment. The median survival in cases of anaplastic astrocytoma is considerably longer, 2 to 4 years. Viewed from another perspective, in a recent large series, the 18-month postoperative survival was 15 percent in patients with glioblastoma and 62 percent in those with anaplastic astrocytoma.

**Astrocytoma (Well-Differentiated Astrocytoma)**

The well-differentiated astrocytomas (grades I and II in former classifications), which constitute between 25 and 30 percent of cerebral gliomas, may occur anywhere in the brain or spinal cord. Favorited sites are the cerebrum, cerebellum, hypothalamus, optic nerve and chiasm, and pons. In general, the location of the tumor appears to be influenced by the age of the patient. Astrocytomas of the cerebral hemispheres arise mainly in adults in their third and fourth decades or earlier; astrocytomas in other parts of the nervous system, particularly the posterior fossa and optic nerves, are more frequent in children and adolescents. These tumors are classified further according to their histologic characteristics: protoplasmic or fibrillary; gemistocytic (enlarged cells distended with hyaline and eosinophilic material); pilocytic (elongated, bipolar cells); and mixed astrocytoma-oligodendroglioma types. The most common type is composed of well-differentiated fibrillary astrocytes. The tumor cells contain glial fibrillary acidic protein (GFAP), which is a useful diagnostic marker in biopsy specimens. Some cerebral astrocytomas, as already noted, present as mixed astrocytomas and glioblastomas. The most common low-grade fibrillary type corresponds to a WHO grade II and is distinguished from the more benign WHO grade I pilocytic tumor (see page 578). The rarer pleomorphic xanthoastrocytoma was also classed as WHO II. These distinctions correlate to a large degree with the biologic behavior of the astrocytomas and therefore have prognostic importance.

Cerebral astrocytoma is a slowly growing tumor of infiltrative character with a tendency in some cases to form large cavities or pseudocysts. Other tumors of this category are noncavitating and appear grayish white, firm, and relatively avascular, almost indistinguishable from normal white matter, with which they merge imperceptibly. Fine granules of calcium may be deposited in parts of the tumor, but this finding in a slow-growing intracerebral tumor is more characteristic of an oligodendroglioma. The CSF is cellular; the only abnormalities in some cases are the increased pressure and protein content. The tumor may distort the lateral and third ventricles and displace the anterior and middle cerebral arteries (seen in CT scans, MR arteriograms, and conventional angiograms; see Fig. 31-3).

In about half of patients with astrocytoma, the opening symptom is a focal or generalized seizure, and between 60 and 75 percent of patients have recurrent seizures in the course of their illness. Other subtle cerebral symptoms follow after months, sometimes after years. Headaches and signs of increased intracranial pressure are relatively late occurrences.

MRI may be helpful in distinguishing the more frequent fibrillary from pilocytic astrocytomas. Pilocytic types are sharply demarcated, with smooth borders and little edema. On T1-weighted MRI, they are isointense or hypointense; on T2 sequences, hyperintense, and there tends to be marked enhancement after gadolinium infusion. Cyst formation and small amounts of calcium are common, especially in cerebellar tumors. The fibrillary tumors have a less stereotyped appearance, generally taking the form of a hypodense mass with less well defined borders and little or no contrast enhancement (Fig. 31-3).
In children, the tumor is usually in the cerebellum (Fig. 31-4) and declares itself by some combination of gait unsteadiness, unilateral ataxia, and increased intracranial pressure (headaches, vomiting). In contrast to glioblastoma, the average survival period after the first symptom is 5 to 6 years in cerebral astrocytomas and 8 years or more in cerebellar ones.

Excision of part of a cerebral astrocytoma, particularly the cystic part, may allow survival in a functional state for many years. The cystic astrocytoma of the cerebellum is particularly benign in its overall behavior. In such cases, resection of the tumor nodule is of singular importance in preventing a recurrence. In recent series, the rate of survival 5 years after successful surgery has been over 90 percent (Pencealet al). The outcome is less assured when the tumor also involves the brainstem and cannot be safely resected.

The natural history of the low-grade gliomas is to grow slowly and eventually undergo malignant transformation. The duration of progression and the latency of recurrence with modern treatment may extend for many years. A survey of the outcome of these low-grade supratentorial tumors showed that 10-year survival after operation was from 11 to 40 percent provided that 5300 cGy was given postoperatively (Shaw et al). In younger patients, particularly if the neurologic examination is normal or nearly so, radiation can be delayed and the course of the tumor evaluated by frequent imaging procedures. A number of studies have come to the conclusion that delaying radiation in younger patients may avoid the consequences of dementia and hypopituitarism (see editorial by Peterson and DeAngelis), but others have suggested that the tumor itself and anticonvulsant drugs cause more difficulty than high-dose radiation. Lacking any clear benefit on survival, it seems to us that radiation should be withheld initially. Nevertheless, an increase in seizures or worsening neurologic signs then presses one to turn to radiation or further surgery. Repeated operations prolong life in some patients; chemotherapy has as yet no established place in the treatment of low-grade pure astrocytomas. However, tumors with an oligodendroglial component may respond well to combination chemotherapy used for the treatment of anaplastic oligodendroglioma, as described below.

The special features of astrocytomas of the pons, hypothalamus, optic nerves, and chiasm, which produce highly characteristic clinical syndromes and do not behave like a cerebral mass, are discussed further on in this chapter.

**Gliomatosis Cerebri**  In this variant of high-grade glioma there is a diffuse infiltration of neoplastic glial cells, involving much of one or both cerebral hemispheres with sparing of neuronal elements but without a discrete tumor mass being identified. Whether this type of “gliomatosis” represents neoplastic transformation of multicentric origin or direct spread from one or more small neoplastic foci is not known. For these reasons, the tumor is impossible to classify (or to grade) using the conventional brain tumor schemes.

Many small series of gliomatosis cerebri have been reported since Nevin introduced the term in 1938, but no truly distinctive clinical picture has emerged (Dunn and Kernohan). Impairment of intellect, headache, seizures, and papilledema are the major manifestations and do not set these cases apart on a clinical basis from the malignant astrocytoma, in which the tumor may also be more widespread than the macroscopic picture suggests. If there is a syndrome that can be associated early on with gliomatosis, in our experience it has been a nondescript frontal lobe abnormality, sometimes mistaken for depression or a subacute dementia, or pseudobulbar palsy may be the first manifestation. The prognosis is poor, generally measured in months from the time of diagnosis.

CT and MRI reveal small ventricles and one or more large confluent areas of signal change (Fig. 31-5). Imaging studies characteristically show the tumor crossing and thickening the corpus callosum. Contrast and gadolinium enhancement tend to be scant,
differentiating the tumor from cerebral lymphoma, which otherwise may give a similar appearance. The spinal fluid is acellular, with slight elevation of protein.

**Treatment** These tumors are too infrequent for categorical judgments to be made regarding therapy, but the overall response to any treatment has been disappointing and the prognosis, as mentioned, is very poor. Corticosteroids have little clinical effect, possibly because of a paucity of edema. Most trials have suggested a benefit of radiation treatment, but the absolute prolongation of life has been only several weeks (Leibel et al). The addition of chemotherapy may confer a marginal further benefit when survival at one year is considered. When a large region is infiltrated, particularly in the temporal lobe, surgical debulking may prolong life, but otherwise surgery is futile.

**Oligodendroglioma** This tumor was first identified by Bailey and Cushing in 1926 and described more fully by Bailey and Bucy in 1929. The tumor is derived from oligodendrocytes or their precursor cells and may occur at any age, most often in the third and fourth decades, with an earlier peak at 6 to 12 years. It is relatively infrequent, constituting about 5 to 7 percent of all intracranial gliomas. From the time of its original descriptions, it was recognized as being more benign than the malignant astrocytoma. Males outnumber females 2:1. In some cases the tumor may be recognized at surgery by its pink-gray color and multinodular form, its relative avascularity and firmness (slightly tougher than surrounding brain), and its tendency to encapsulate and form calcium and small cysts. Most oligodendrogliomas, however, are grossly indistinguishable from other gliomas, and a proportion—up to half in some series—are mixed oligoastrocytomas, suggesting that their precursor cell is pluripotential.

The neoplastic oligodendrocyte has a small round nucleus and a halo of unstained cytoplasm ("fried egg" appearance). The cell processes are few and stubby, visualized only with silver carbonate stains. Some of the glioblastillary oligodendrocytes have intense immunoreactivity to glial fibrillary acidic protein (GFAP), similar to normal myelin-forming oligodendrocytes. Microscopic calcifications are observed frequently, both within the tumor and in immediately adjacent brain tissue.

The most common sites of this tumor are the frontal and temporal lobes (40 to 70 percent), often deep in the white matter, with one or more streaks of calcium but little or no surrounding edema. Sometimes the tumor presents in a lateral ventricle; it is rarely found in other parts of the nervous system. By extending to the pial surface or ependymal wall, the tumor may metastasize distantly in ventricular and subarachnoid spaces, accounting for 11 percent of the Polmeeter and Kernohan series of gliomas with meningeal dissemination (less frequent than medulloblastoma and glioblastoma; see also Yung et al). The tumor does not lend itself to the glial grading scale, but malignant degeneration, evidenced by greater cellularity and by numerous and abnormal mitoses, and necrosis occur in about one-third of the cases. Such anaplastic tumors are sometimes called oligodendroglioblastomas. In the oligoastrocytomas, either cell type may be anaplastic.

The typical oligodendroglioma grows slowly. As with astrocytomas, the first symptom in more than half the patients is a focal or generalized seizure; seizures often persist for many years before other symptoms develop. Approximately 15 percent of patients enter the hospital with early symptoms and signs of increased intracranial pressure; an even smaller number have focal cerebral signs (hemiparesis). Much less frequent are unilateral extrapyramidal rigidity, cerebellar ataxia, Parinaud syndrome, intratumoral hemorrhage, and meningeal oligodendrogliosis (cranial-spinal nerve palsies, hydrocephalus, lymphocytes and tumor cells in CSF).

The appearance on imaging studies is variable, but the most typical is a hypodense mass near the cortical surface with relatively well-defined borders. Calcium is seen in CT scans in more than half the cases and is a helpful diagnostic sign (Fig. 31-6), but it should also raise the possibility of an arteriovenous malformation, a low-grade astrocytoma, or a meningioma. Oligodendrogliomas generally do not demonstrate contrast enhancement, but anaplastic ones and the mixed tumors may do so.

In recent years, a remarkable degree of progress has been made in understanding the genetic aberrations within these tumors and the relationship of these genes to the prognosis and response to therapy. Specifically, loss of certain alleles on chromosome 1p is predictive of a high degree of responsiveness to the below-described PCV chemotherapy regimen, and a similar loss on chromosome 19p is associated with long survival.

**Treatment** Surgical excision followed by radiation therapy has been the conventional treatment for oligodendroglioma. However, because of uncertainty as to the histologic classification of many of the reported cases, it is not clear whether radiation therapy is attended by longer survival. Well-differentiated oligodendrogliomas should probably not receive radiation. The discovery by Cairncross and MacDonald of considerable importance, as mentioned earlier, is that many oligodendrogliomas, especially anaplastic ones, respond impressively to chemotherapeutic agents, particularly to a PCV regimen—a combination of procarbazine, lomustine (CCNU), and vincristine given in approximately six cycles. Mixed oligodendrogliomas and astrocytomas should generally be treated like astrocytomas, with the addition of chemotherapy to manage the oligodendroglial component, as recommended in some
centers. Of great interest has been the identification by Cairncross and others of genetic markers in anaplastic oligodendrogliomas, and possibly low-grade ones as well (mainly on chromosomes 1p and 19q), that predict a remarkable chemoresponsivity to the PCV regimen and prolonged survival, as mentioned above. For example, of 50 patients who had loss of these regions on 19p but no other genetic aberrations, the median survival was over 10 years. These findings are just being adopted into general clinical practice, and it is likely that refinements of them will be soon (see Louis et al and Reifenberger and Louis).

Ependymoma (See also page 567) This tumor proves to be more complex and variable than other gliomas. Correctly diagnosed by Virchow as early as 1863, its origin from ependymal cells was first suggested by Mallory, who found the typical blepharoplasts (small, darkly staining cytoplasmic dots that are the basal bodies of the cilia as seen by electron microscopy.). Two types were recognized by Bailey and Cushing: one was the ependymoma, and the other, with more malignant and invasive properties, the ependymoblastoma. More recently a myxopapillomatous type, localized exclusively in the filum terminale of the spinal cord, has been identified (see Chap. 44).

Ependymomas are derived from ependymal cells—i.e., the cells lining the ventricles of the brain and the central canal of the spinal cord; this is the most common glioma of the spinal cord. These cells have both glial and epithelial characteristics. As one might expect, the tumors grow either into the ventricle or adjacent brain tissue. The most common cerebral site is the fourth ventricle; less often, they occur in the lateral or third ventricles (page 567). In the spinal cord, most ependymomas originate in the lumbosacral regions, from the conus medullaris or filum terminale. Grossly, those in the fourth ventricle are grayish pink, firm, cauliflower-like growths; those in the cerebrum, arising from the wall of the lateral ventricle, may be large (several centimeters in diameter), reddish gray, and softer and more clearly demarcated from adjacent tissue than astrocytomas, but they are not encapsulated. The tumor cells tend to form rosettes with central lumens or, more often, circular arrangements around blood vessels (pseudorosettes). Some ependymomas, called epithelial, are densely cellular; others form papillae. Some of the well-differentiated fourth ventricular tumors are probably derived from subependymal astrocytes (see later in this chapter and also Fig. 31-12).

Anaplastic ependymomas are identified by their high mitotic activity and endothelial proliferation, nuclear atypia, and necrosis. The correlations between histopathologic features and clinical outcomes have not been well defined, however.

Approximately 6 percent of all intracranial gliomas are ependymomas, the percentage being slightly higher in children (8 percent). About 40 percent of the infratentorial ependymomas occur in the first decade of life, a few as early as the first year. The supratentorial ones are more evenly distributed among all age groups, but in general the age incidence is lower than that of other malignant gliomas.

The symptomatology depends on the location of the growth. The clinical manifestations of fourth ventricular tumors are described further on in this chapter; the point to be made here is the frequent occurrence of hydrocephalus and signs of raised intracranial pressure (manifest in children by lethargy, nausea, vomiting, and papilledema). Cerebral ependymomas otherwise resemble the other gliomas in their clinical expression. Seizures occur in approximately one-third of the cases.

The imaging characteristics are rather different from those of other tumors. In the CT scan one observes a well-demarcated heterogeneous hyperdense mass with fairly uniform contrast enhancement. Calcification and some degree of cystic change are common in supratentorial tumors but less so in infratentorial ones. There are mixed signal characteristics on MRI, generally hypointense on T1 sequences and hyperintense on T2. An intraventricular location supports the diagnosis of ependymoma, but meningioma and a number of other tumors may be found in this location.

Treatment It is notable that the interval between the first symptom and the diagnosis ranges from 4 weeks, in the most malignant types, to 7 to 8 years. In a follow-up study of 101 cases in Norway, where ependymomas made up 1.2 percent of all primary intracranial tumors and 32 percent of intraspinal tumors, the postoperative survival was poor. Within a year, 47 percent of the patients had died, although 13 percent were alive after 10 years. Doubtless the prognosis depends on the degree of anaplasia (Mørk and Løken), the location of the tumor, and whether it is operable. Surgical removal is supplemented by radiation therapy, particularly to address the high rate of seeding of the ventricles and spinal axis. In the treatment of cerebral ependymoblastomas, antitumor drugs are often used in combination with radiation therapy.

Meningioma (See also page 577) This is a benign tumor, first illustrated by Matthew Baillie in his Morbid Anatomy (1787) and first recognized by Bright, in 1831, as originating from the dura mater or arachnoid. It was analyzed from every point of view by Harvey Cushing and was the subject of one of his most important monographs. Meningiomas represent about 15 percent of all primary intracranial tumors; they are more common in women than in men (2:1) and have their highest incidence in the sixth and seventh decades. Some are familial. There is evidence that persons who have undergone radiation therapy to the scalp or cranium are vulnerable to the development of meningiomas and that the tumors appear at an earlier age in such individuals (Rubinstein et al). There are a number of reports of a meningioma developing at the site of previous trauma, such as a fracture line, but the association is uncertain.

The most frequent genetic defects of meningiomas are truncating (inactivating) mutations in the neurofibromatosis 2 gene (merlin) on chromosome 22q. These are present in the great majority of certain meningiomas (e.g., fibroblastic and transitional types), but not others. Merlin deletions probably also play a role in those instances in which there is a loss of the long arm of chromosome 22. In meningiomas of both the sporadic and neurofibromatosis (NF2)-associated types, other genetic defects are found, including deletions on chromosomes 1p, 6q, 9p, 10q, 14q, and 18q. Meningiomas also elaborate a variety of soluble proteins, some of which (vascular endothelial growth factor) are angiogenic and relate to both the highly vascularized nature of these tumors and their prominent surrounding edema (see Lamszus for further details). Some meningiomas contain estrogen and progesterone receptors. The implications of these findings are not yet clear but may relate to the increased incidence of the tumor in women, its tendency to enlarge during pregnancy, and an association with breast cancer.

The precise origin of meningiomas is still not settled. According to Rubinstein, they may arise from dural fibroblasts, but in our opinion, they are more clearly derived from arachnoidal (meningotheial) cells, in particular from those forming the arachnoid villi. Since the clusters of arachnoidal cells penetrate the dura in largest number in the vicinity of venous sinuses, these are the
sites of predilection for the tumor. Grossly, the tumor is firm, gray, and sharply circumscribed, taking the shape of the space in which it grows; thus, some tumors are flat and plaque-like, others round and lobulated. They may indent the brain and acquire a pia-arachnoid covering as part of their capsule, but they are clearly demarcated from the brain tissue (extra-axial) except in the unusual circumstance of a malignant invasive meningioma. Rarely, they arise from arachnoidal cells within the choroid plexus, forming an intraventricular meningioma.

Microscopically, the cells are relatively uniform, with round or elongated nuclei, visible cytoplasmic membrane, and a characteristic tendency to encircle one another, forming whorls and psammoma bodies (laminated calcific concretions). A notable electron microscopic characteristic is the formation of very complex interdigitations between cells and the presence of desmosomes (Kepes). Cushing and Eisenhardt and, more recently, the World Health Organization (Lopes et al) have divided meningiomas into many subtypes depending on their mesenchymal variations, the character of the stroma, and their relative vascularity, but the value of such classifications is debatable. Currently neuropathologists recognize a meningothelial (syncytial) form as being the most common. It is readily distinguished from other similar but non-meningothelial tumors such as hemangiopericytomas, fibroblastomas, and chondrosarcomas.

The usual sites of meningioma are the sylvian region, superior parasagittal surface of the frontal and parietal lobes, olfactory groove, lesser wing of the sphenoid bone, tuberculum sellae, superior surface of the cerebellum, cerebellopontine angle, and spinal canal. Some meningiomas—such as those of the olfactory groove, sphenoid wing, and tuberculum sellae—express themselves by highly distinctive syndromes that are diagnostic in themselves; these are described further on in this chapter. Rarely, they are multiple. Inasmuch as they extend from the dural surface, they often invade and erode the cranial bones or excite an osteoblastic reaction, even giving rise to an exostosis on the external surface of the skull. The following remarks apply to meningiomas of the parasagittal, sylvian, and other surface areas of the cerebrum.

Small meningiomas, less than 2.0 cm in diameter, are often found at autopsy in middle-aged and elderly persons without having caused symptoms. Only when they exceed a certain size and indent the brain do they alter function. The size that must be reached before symptoms appear varies with the size of the space in which the tumor grows and the surrounding anatomic arrangements. Focal seizures are often an early sign of meningiomas that overlie the cerebrum. The parasagittal frontoparietal meningioma may cause a slowly progressive spastic weakness or numbness of one leg and later of both legs, and incontinence in the late stages. The sylvian tumors are manifest by a variety of motor, sensory, and aphasic disturbances in accord with their location, and by seizures.

In the past, before brain imaging techniques became available, the meningioma often gave rise to neurologic signs for many years before the diagnosis was established, attesting to its slow rate of growth. Even now some tumors reach enormous size, to the point of causing papilledema, before the patient comes to medical attention. A few may be detected in plain films or in CT scans in individuals with unrelated neurologic diseases. Increased intracranial pressure eventually occurs, but it is less frequent with meningiomas than with gliomas.

As mentioned above, the diagnosis of meningiomas is greatly facilitated by their ready visualization with contrast-enhanced CT and MRI (Figs. 31-7 and 31-8) and by arteriography, all of which reveal their tendency to calcify and their prominent vascularity. These changes are reflected by homogeneous contrast enhancement.
Treatment variable. The CSF protein is usually elevated.

Gadolinium. The amount of edema surrounding the tumor is highly cause, they may be difficult to see on MRI scans performed without fusion; calcification at the outer surface or heterogeneously isointense or slightly hyperintense unless enhanced by contrast in-

The skull or the falcial or tentorial dura. On the CT scan they are sometimes lobulated, with one edge abutting the inner surface of the skull or the falcial or tentorial dura. On the CT scan they are isointense or slightly hyperintense unless enhanced by contrast inf-

fusion; calcification at the outer surface or heterogeneously throughout the mass is common. Except for the mass effect they cause, they may be difficult to see on MRI scans performed without gadolinium. The amount of edema surrounding the tumor is highly variable. The CSF protein is usually elevated.

Tumors that lie beneath the hypothalamus, along the me-

dial part of the sphenoid bone and parasellar region, or anterior to the brainstem are the most difficult to remove surgically. By in-

vading adjacent bone, they may become impossible to remove to-

tally. Carefully planned radiation therapy including gamma-knife or proton beam treatment is beneficial in cases that are inoperable. Carefully planned radiation therapy including gamma-knife or proton beam treatment is beneficial in cases that are inoperable and when the tumor is incompletely removed or shows malignant characteristics (Kornblith et al). Smaller tumors at the base of the skull can be obliterated or greatly reduced in size by focused ra-

diation, probably with less risk than surgery would pose (Chang and Alder). Conventional chemotherapy is probably ineffective; hormonal therapy with the antiprogestin agents has been used with variable results but is still under study (McCutcheon). More re-

cently it has been suggested that hydroxyurea has the capacity to shrink unresectable and recurrent meningiomas (Schrell et al); this mode of treatment is still being evaluated.

Primary Cerebral Lymphoma As mentioned earlier, this tumor has assumed increasing significance in the last two decades because of its frequency in AIDS and other immunosuppressed states. How-

ever, it is also occurring with increased frequency in immunocompetent persons—a finding without evident explanation (although theories abound). There is a preponderance of men, with the peak incidence in the fifth through seventh decades, or in the third and fourth decades in patients with AIDS.

For many years, the cell of origin of this tumor was thought to be the reticulum cell and the tumor was regarded as a reticulum cell sarcoma. The meningeal histiocyte and microgliocytes are the equivalent cells in the brain to the reticulum cell of the germinal centers of lymph nodes. Later, the intracerebral lymphocytes and lymphoblasts, also prominent components of the tumor, led to its reclassification as a lymphoma (large-cell histiocytic type). It is appreciated, on the basis of immunocytochemical studies, that the tumor cells are B lymphocytes. There is a fine reticulum reaction between the reticulum cells derived from fibroblasts and microglia or histiocytes. As matters now stand, most pathologists believe that the B lymphocyte or lymphoblast is the tumor cell, whereas the fine reticulum and “microgliocytes” are secondary interstitial re-

actions. We tend to believe that both cell types are present and have not entirely abandoned the notion of an origin in a reticulum cell.

In contrast, T-cell lymphomas of the nervous system are rare but do occur in both immunocompetent patients and in immuno-
suppressed patients with AIDS. Since the brain is devoid of lymphatic tissue, it is uncertain how this tumor arises; one theory holds that it represents a systemic lymphoma with a particular proclivity to metastasize to the nervous system. This seems unlikely to the authors; systemic lymphomas of the usual kind rarely metastasize, as discussed further on, under “Involvement of the Nervous System in Systemic Lymphoma.”

These tumors may arise in any part of the cerebrum, cerebel-

lum, or brainstem, with 60 percent being in the cerebral hemi-

spheres; they may be solitary or multifocal. A periventricular local-

ization is common. Vitreous, uveal, and retinal (ocular) involvement occurs in 10 to 20 percent of cases; here vitreous biopsy may be diagnostic, but it is not often performed. (Two-thirds of patients with ocular lymphoma will have cerebral involvement within a year.) The pia-arachnoid may be infiltrated, and a purely meningeal form of B-cell lymphoma that involves peripheral and cranial nerves is also known. Most such cases of what has been termed neurolymphomatosis present with painful, predominantly motor polyradiculopathies. One such patient of ours presented with a flaccid paraparesis and back and sciatic pain; MRI showed tumor infiltrating the cauda equina nerve roots and contiguous meninges. Lai and colleagues have presented evidence that, in advanced cases that were autopsied, microscopic deposits of tumor were found in many regions of the brain and not solely in areas indicated by nodular enhancement on MRI. Whether this indicates a widespread or multifocal origin of brain lymphoma is not clear.

The primary large-cell lymphoma forms a pinkish gray, soft, ill-defined, infiltrative mass in the brain, difficult at times to distin-
guish from a malignant glioma. Pervascular and meningeal spread results in shedding of cells into the CSF, accounting perhaps for the multifocal appearance of the tumor in almost half of the cases. The tumor is highly cellular and grows around and into blood ves-

Figure 31-8. Gadolinium-enhanced MRI of meningioma. Large subfrontal mass with central calcification and surrounding vasogenic edema. Homogeneous enhancement is characteristic of the tumor.
sels (“angiocentric” pattern); it elicits little tendency to necrosis. The nuclei are oval or bean-shaped with scant cytoplasm, and mitotic figures are numerous. B-cell markers applied to fixed tissue define the lymphoblastic cell population as monoclonal and identify the tumor cell type. The stainability of reticulum and microglial cells, the latter by Hortega’s silver carbonate method, also serves to distinguish this tumor microscopically. There is no tumor tissue outside the brain.

It should also be mentioned that several of our cases of meningeal and cranial nerve lymphoma with similar histologic characteristics to primary CNS lymphoma were complications of lymphatic leukemia.

Primary lymphoma involving the cerebral hemispheres pursues a clinical course somewhat similar to that of the glioblastoma but with a vastly different response to treatment. The interval between the first symptom and operation has been approximately 3 months. Behavioral and personality changes, confusion, dizziness, and focal cerebral signs predominate over headache and other signs of increased intracranial pressure as presenting manifestations. Seizures may occur but are less common in our experience than they are as the introductory feature of gliomas. Most cases occur in adult life, but some have been observed in children, in whom the tumor may simulate the cerebellar symptomatology of medulloblastoma. Rare cases that remit spontaneously appear in the literature from time to time.

The finding on CT and MRI of one or several dense, homogeneous, and enhancing periventricular masses is characteristic (Fig. 31-9). However, nodular, ring-like enhancement also occurs, and any part of the brain may be involved. The radiologic appearance in AIDS patients is less predictable and may be difficult to distinguish from that of toxoplasmosis or another process with which lymphoma may coexist. Characteristic is the radiographic disappearance of the lesions or complete but transient resolution of contrast enhancement in response to corticosteroids. Lymphocytic and mononuclear pleocytosis of CSF is more frequent than with gliomas and metastatic tumors. The immunohistochemical demonstration in CSF of monoclonal lymphocytes or an elevated beta microglobulin points to leptomeningeal spread of the tumor (Li et al), but frequently the diagnosis is not possible from CSF cytologic examination alone.

As already indicated, patients with AIDS and less common immunodeficiency states, such as the Wiskott-Aldrich syndrome and ataxia-telangiectasia, and those receiving immunosuppressive drugs for long periods, such as patients undergoing renal transplantation, are particularly liable to develop this type of primary cerebral lymphoma. Many of the tumors in immunosuppressed patients contain the Epstein-Barr virus (EBV) genome, suggesting a pathogenetic role for the virus (Bashir and colleagues); however, the EBV genome has been found in the lymphoma cells in both immunocompetent and immunosuppressed patients (Hochberg and Miller). Sometimes this tumor appears as a complication of an obscure medical condition such as salivary and lacrimal gland enlargement (Mikulicz syndrome). Stereotactic needle biopsy is the preferred method of establishing the histologic diagnosis in sporadic cases. But in AIDS patients, the differential diagnosis of a solitary brain nodule that is suspected to be lymphoma is aided by the response, or lack thereof, to treatment for toxoplasmosis, the main alternative diagnosis to brain lymphoma (see page 646). Reduction in the size of the lesion(s) with antimicrobial drugs makes biopsy unnecessary.

**Treatment** Because the tumors are deep and often multicentric, surgical resection is ineffective except in rare instances. Treatment with cranial irradiation and corticosteroids often produces a partial or, rarely, complete response, as remarked above, but the tumor recurs in more than 90 percent of patients. Until recently the median survival of patients treated in this way has been 10 to 18 months.
but less in those with AIDS or in individuals who are otherwise immunocompromised. In immunocompetent patients, the addition of intrathecal methotrexate and intravenous cytosine arabinoside increases median survival to more than 3 years (DeAngelis), and apparent cure is not unknown. However, this combined treatment is associated with a high risk of a leukoencephalopathy (see further on and Fig. 31-23) and causes considerable unpleasant systemic side effects.

More recent regimens, as outlined by Glass and colleagues, consist of several cycles of intravenous methotrexate (3.5 g/m²) and citrovorum, administered at 2- to 3-week intervals and at times continued indefinitely if tolerated. The side effects of these treatments are modest and there is no need for repeated lumbar punctures or the placement of an Ommaya reservoir. Most of our patients have not developed mucositis or the other of the usual side effects of this type of chemotherapy. Radiation treatment may be used subsequently, but there is then a higher incidence of delayed leukoencephalopathy and dementia. Ocular lymphoma is eradicated only by radiation. Corticosteroids are added at any point as needed to control prominent neurologic symptoms. The median survival time has been in the range of 3.5 years with intravenous methotrexate alone and 4 years or more if radiation is given subsequently. Some patients are alive at 10 years.

**Metastatic Carcinoma** Among secondary intracranial tumors, only metastatic carcinoma occurs with high frequency. Occasionally one encounters a rhabdomyosarcoma, Ewing tumor, carcinoid, etc., but these tumors are so infrequent that their cerebral metastases seldom become a matter of diagnostic concern. The pathophysiology of metastatic carcinoma—the complex biologic mechanisms that govern the detachment of tumor cells from the primary growth, their transport to distant tissues, and their implantation on the capillary endothelium of the particular organ in which they will eventually grow—has been well reviewed by Rusciano and Burger and by Posner.

Autopsy studies disclose intracranial metastases in approximately 25 percent of patients who die of cancer (Posner). About 80 percent of the metastases are in the cerebral hemispheres and 20 percent in posterior fossa structures, corresponding roughly to the relative size and weights of these portions of the brain and their blood flow. Cancers of the pelvis and colon are exceptional in this respect, having a somewhat higher tendency than this to spread to the posterior fossa. Intracranial metastases assume three main patterns—those to the skull and dura, those to the brain itself, and those spreading diffusely through the craniospinal meninges (meningeal carcinomatosis). Almost as common as intracranial metastases are those to the spinal bones, which in time cause compression of the spinal cord. This problem is discussed in Chap. 44. Metastatic deposits in the spinal cord itself are infrequent but are seen from time to time; they are more common, for example, than a paraneoplastic necrotic myelopathy (see further on).

**Metastases to the skull and dura** can occur with any tumor that metastasizes to bone, but they are particularly common with carcinoma of the breast and prostate and with multiple myeloma. These secondary deposits usually occur without metastases to the brain itself and reach the skull either via the systemic circulation (as in carcinoma of the breast) or via Batson’s vertebral venous plexus—a valveless system of veins that runs the length of the vertebral column from the pelvic veins to the large venous sinuses of the skull, bypassing the systemic circulation (the route supposedly taken by carcinoma of the prostate). Metastatic tumors of the convexity of the skull are usually asymptomatic, but those at the base may implicate the cranial nerve roots or the pituitary body. Bony metastases are readily recognized on bone and CT scans and most are evident in plain films. Occasionally, a carcinoma metastasizes to the subdural surface and compresses the brain, like a subdural hematoma. Others, perhaps most, are asymptomatic.

Apart from the above, most carcinomas reach the brain by hematogenous spread. Almost one-third of them originate in the lung and half this number in the breast; melanoma is the third most frequent source in most series, and the gastrointestinal tract (particularly the colon and rectum) and kidney are the next most common. Carcinomas of the gallbladder, liver, thyroid, testicle, uterus, ovary, pancreas, etc., account for the remainder. Tumors originating in the prostate, esophagus, oropharynx, and skin (except for melanoma) almost never metastasize to the substance of the brain. From a somewhat different point of view, certain neoplasms are particularly prone to metastasize to the brain—75 percent of melanomas do so, 57 percent of testicular tumors, and 35 percent of bronchial carcinomas, of which 40 percent are small-cell tumors (Posner and Chernik). According to those authors, the cerebral metastasis is solitary in 47 percent of cases, a somewhat higher figure than that observed in our practice and reported by others (see Henson and Urich). The metastatic tumors most likely to be single come from kidney, breast, thyroid, and adenocarcinoma of the lung. Small-cell carcinomas and melanomas tend to be multiple.

Generally the cerebral metastasis forms a circumscribed mass, usually solid but sometimes in the form of a ring (i.e., cystic), that excites rather little glial reaction but much regional vasogenic edema. Often edema alone is evident on imaging studies until the administration of contrast exposes small tumor nodules (Fig. 31-10).

Metastases from melanoma and choroeplithelioma are often hemorrhagic, but some from the lung, thyroid, and kidney exhibit this characteristic as well. In a number of these cases, one-quarter in some series, the first manifestation of the metastasis is an intratumoral hemorrhage. The relative frequency of lung cancer makes

*Figure 31-10. Contrast-enhanced CT scan showing multiple metastases from bronchogenic carcinoma. Each lesion is surrounded by edema.*
it the most common metastatic tumor to bleed, even though only a small proportion hemorrhage.

The usual clinical picture of metastatic carcinoma of the brain is much like that of glioblastoma multiforme. Seizures, headache, focal weakness, mental and behavioral abnormalities, ataxia, aphasia, and signs of increased intracranial pressure—all inexcorably progressive over a few weeks or months—are the common clinical manifestations. Also, a number of unusual syndromes may occur. One that presents particular difficulty in diagnosis is a diffuse cerebro disturbance with headache, nervousness, depressed mood, trembling, confusion, and forgetfulness, resembling a relatively rapid dementia from degenerative disease. Cerebellar metastasis, with headache, dizziness, and ataxia (the latter being brought out only by having the patient walk) is another condition that may be difficult to diagnose. Brainstem metastases, most often originating in the lung, are rare but distinctive, giving rise to diplopia, imbalance, and facial palsy as in the characteristic case described by Weiss and Richardson.

Infrequently, the onset of symptoms from brain metastases is relatively abrupt or even “stroke-like” rather than insidious. Some cases of sudden onset can be explained by bleeding into the tumor and others perhaps by tumor embolism, causing cerebral infarction with early regression of symptoms and later progression from the metastasis left in its wake. In most cases, the explanation is not known. Also, nonthrombolic (marantic) endocarditis with cerebral embolism must be suspected when a stroke-like event occurs in a tumor patient. It is not unusual for one or other of these neurologic manifestations to precede those of the discovery of a pancreatic, bowel, gastric, breast, or lung carcinoma.

When any of the several clinical syndromes due to metastatic tumor is fully developed, diagnosis is relatively easy. If only headache and vomiting are present, a common error is to attribute them to migraine or tension headache (page 158). One should invoke such explanations only if the patient has the standard symptoms of one of these conditions. CT scanning, with and without contrast, will detect practically all sizable (1 cm) metastases. In addition, MRI will expose associated leptomeningeal disease and is more sensitive to small cerebellar deposits. Multiple nodular deposits of tumor in the brain on imaging studies most clearly distinguish metastatic cancer from other tumors but at the same time raise the possibility, on radiologic grounds, of brain abscesses.

Solitary metastatic disease first must be distinguished from a primary tumor of the brain. Also, metastases must not be confused with certain neurologic syndromes that sometimes accompany carcinoma but are not due to the invasion or compression of the nervous system by tumor. The latter, referred to as paraneoplastic disorders, include polyneuropathy (especially with carcinoma of the lung), polymyositis, cerebellar degeneration (ovarian and other carcinomas and Hodgkin disease), necrotizing myelopathy (rare), and certain cerebral disorders (progressive multifocal leukoencephalopathy and “limbic encephalitis”). These paraneoplastic syndromes are discussed further on, under “Remote Effects of Neoplasia on the Nervous System.”

In addition to the aforementioned conditions, there are many patients with cancer who exhibit symptoms of an altered mental state without evidence of metastases or a recognizable paraneoplastic disorder. These mental symptoms usually arise on the basis of systemic metabolic disturbances (hypercalcemia in particular), drugs, and psychologic reactions, some of which have yet to be clearly delineated. Problems of this type were noted in a high percentage of cancer patients seen in consultation at the Memorial Sloan-Kettering Cancer Center (Clouston et al) and in our own patients.

**Treatment** The treatment of secondary (metastatic) tumors of the nervous system is undergoing change. Most current programs utilize various combinations of corticosteroids, brain irradiation, surgical intervention, and chemotherapy (see review by O’Neill et al). Corticosteroids produce prompt improvement, but sustained use is restricted by their many side effects and eventual loss of efficacy. Most patients also temporarily benefit from the use of whole-brain irradiation, usually administered over a 2-week period, in 10 doses of 300 cGy each. Focused radiotherapy (“gamma knife”) is a suitable alternative.

In patients with a single parenchymatous metastasis (shown to be solitary by gadolinium-enhanced MRI), surgical extirpation may be undertaken provided that growth of the primary tumor and its systemic metastases is under good control and the cerebral metastasis is accessible to the surgeon and not located in a strategic motor or language area of the brain; usually excision is followed by radiation therapy to the entire brain. Patchell and coworkers have shown that survival and the interval between treatment and recurrence are longer and that the quality of life is better in patients treated in this way than in comparable patients treated with whole-brain radiation alone. Single or dual metastases from renal cell cancer, melanoma, and adenocarcinoma of the gastrointestinal tract lend themselves best to surgical removal, sometimes repeatedly. Several clinical trials in patients with small-cell carcinoma of the lung suggest that prophylactic irradiation of the neuraxis decreases the occurrence of metastases but does not prolong survival (Nugent et al). Also, there is increasing evidence that some metastatic brain tumors are quite sensitive to certain chemotherapeutic agents, especially if the primary tumor is also sensitive. Intrathecal and intraventricular chemotherapy are not thought to be of value in the treatment of parenchymal metastases. Immunotherapy has not yet been widely employed.

The prophylactic use of anticonvulsants is controversial. Some tentative evidence favors their use, but—as mentioned earlier—the incidence of skin reactions is increased when phenytoin is employed and radiation is given. Other studies, some well controlled, have shown no benefit in preventing a first seizure in patients with a primary or secondary brain tumor.

Despite these therapeutic measures, survival is only slightly prolonged. The average period of survival, even with therapy, is about 6 months, but it varies widely and is dominated by the extent of other systemic metastases. Between 15 and 30 percent of patients live for a year and 5 to 10 percent for 2 years; with certain radiosensitive tumors (lymphoma, testicular carcinoma, choriocarcinoma, some breast cancers), survival can be much longer. Patients with bone metastases tend to live longer than those with parenchymatous and meningeal metastases.

**Meningeal Carcinomatosis (“Carcinomatous Meningitis”)** Widespread dissemination of tumor cells throughout the meninges and ventricles, a special form of metastatic cancer, has been the pattern in about 5 percent of cases of adenocarcinoma of breast, lung, and gastrointestinal tract; melanoma; childhood leukemia; and systemic lymphoma. With certain carcinomas, notably gastric in our experience, it may be the first manifestation of a neoplastic illness, although more often the primary tumor has been present and is under treatment.

Headache and backache, often with sciatica, are common but not invariable. Polyradiculopathies (particularly of the cauda
equina), multiple cranial nerve palsies, and a confusional state have been the principal manifestations, and many cases are restricted to one of these subsyndromes. Only a small number have an uncomplicated meningeal syndrome of headache, nausea, and meningismus, but these features develop late in the course of many cases. Delirium, stupor, and coma follow in the pure meningeal syndrome. Focal neurologic signs and seizures may be associated, and somewhat fewer than half the patients develop hydrocephalus. This is among the most deceptive of neurologic diagnoses. It may cause a painful or painless polyradiculopathy and simulate a polyneuropathy; it has several times deceived us into considering the diagnosis of an inflammatory polyneuropathy. The combination of a cranial neuropathy, such as unilateral facial weakness, hearing loss or ocular motor palsy, with bilateral asymmetrical limb weakness is particularly suggestive. The evolution in all these syndromes is generally subacute over weeks with a more rapid phase as the illness progresses.

The diagnosis can be established in most cases by identifying tumor cells in the CSF using flow cytometry, cytospin, centrifugation, or Millipore filtering. More than one examination, using generous quantities of CSF, may be needed. Increased pressure, elevation of protein and low glucose levels, and lymphocytic pleocytosis (up to a hundred but typically much fewer) are other common CSF findings. Nevertheless, in a few patients, the CSF remains persistently normal. Measuring the CSF for certain biochemical markers of cancer—such as lactate dehydrogenase, β-glucuronidase, β2-microglobulin, and carcinoembryonic antigen (CEA)—offers another means of making the diagnosis and following the response to therapy. These markers are most likely to be abnormal in hematologic malignancies but may also be altered in some cases of intracranial infection and parenchymal metastases (Kaplan et al).

In a few of the cases of meningeal carcinomatosis, there are also parenchymal brain metastases.

Also known is a rare primary malignant melanoma of the meninges that acts in a similar way to carcinomatous meningitis. Bloody CSF is a characteristic feature. The prognosis is as bleak as it is for metastatic carcinomatous meningitis.

The prognosis for this condition is quite poor (lymphomatous infiltration is an exception); seldom does the patient survive more than 1 to 3 months, perhaps longer by several weeks if treatment is successful. An encephalopathy due to widespread infiltration of the cerebral meninges is a particularly malevolent sign.

**Treatment** This consists of radiation therapy to the symptomatic areas (cranium, posterior fossa, or spine), followed in selected cases by the intraventricular administration of methotrexate; but these measures rarely stabilize neurologic symptoms for more than a few weeks. The methotrexate is administered into the lateral ventricle via an Ommaya reservoir (10 mg diluted in water) or into the lumbar subarachnoid space through a lumbar puncture needle (12 to 15 mg). Several regimens have been devised, including daily instillation for 3 to 4 days followed by radiation, or methotrexate doses on days 1, 4, 8, 11, and 15. Involvement of the cranial nerves or an encephalopathy due to widespread infiltration of the cranial meninges is treated with whole-brain radiation, 3000 cGy, given in fractions of 300 cGy per day for 10 days. Spinal root infiltration responds to spinal radiation, and regional treatments are helpful temporarily for local seeding of the lumbar roots. The median duration of survival after diagnosis of meningeal carcinomatosis was 6 months in the large series reported by Wasserstrom and colleagues but only 43 days in the series of Sorenson and coworkers. The leukoencephalopathy that may follow the combined use of intrathecal methotrexate and radiation therapy is described below.

The best response to treatment occurs in patients with lymphoma and breast and small-cell lung cancers; cases of meningeal infiltration by other lung cancers, melanoma, and adenocarcinoma do poorly.

**Involvement of the Nervous System in Leukemia** Almost one-third of all leukemic patients have evidence of diffuse infiltration of the leptomeninges and cranial and spinal nerve roots at autopsy (Barcos et al). The incidence is greater in acute than in chronic leukemia and greater in lymphocytic than in myelocytic leukemia; it is also far more frequent in children than in adults. The highest incidence is in children with acute lymphocytic (lymphoblastic) leukemia who relapse after treatment with combination chemotherapy (60 to 70 percent at time of death). The clinical and CSF picture of meningeal leukemia is much the same as that of meningeal carcinomatosis, discussed above, with the qualification that leukemic cells are more likely to be found by cytologic examination of the spinal fluid. The treatment of the two disorders is also similar.

The studies of Price and Johnson demonstrated that CNS leukemia is primarily a pial disease. The earliest evidence of leukemia is detected in the walls of pial veins, with or without cells lying freely in the CSF. The leukemic infiltrate in our pathologic material has extended to the deep perivascular spaces, where the pial-glial membrane often confines it; at this stage the CSF consistently contains leukemic cells. Depending on the severity of meningeal involvement, transgression of the pial-glial membrane eventually occurs, with varying degrees of superficial parenchymal infiltration by collections of leukemic cells. Hemorrhages of varying sizes are another common complication and are sometimes lethal. Chloasma, a solid green-colored mass of myelogenous leukemia cells, may affect the dura or, less often the brain, but it is distinctly uncommon.

Cranial irradiation, combined with methotrexate given intrathecally or intravenously, has been effective in the prevention and treatment of meningeal involvement in childhood leukemia. However, in a significant number of patients, it has given rise to a distinctive *necrotizing leukoencephalopathy*. This neurologic complication may appear within several days to months after the last administration of methotrexate and several months after completion of radiotherapy (Robain et al). The leukoencephalopathy occurs most frequently and is most severe when all three modalities of treatment, i.e., cranial irradiation and intrathecal and intravenous methotrexate, are used. The initial symptoms—consisting of apathy, drowsiness, depression of consciousness, and behavioral disorders—evolve over a few weeks to include cerebellar ataxia, spasticity, pseudobulbar palsy, extrapyramidal motor abnormalities, and akinetic mutism. Hypodense areas of varying size appear in the CT scan but—unlike the case with tumor metastases—there is no contrast enhancement. By MRI these methotrexate lesions are hyperintense in T2-weighted images, but compared with pure radiation necrosis (see further on), they have poorly demarcated borders. In some patients the condition stabilizes or improves, with corresponding resolution of the lesions. More often the patient is left with severe persistent sequelae; in most, death occurs within several weeks or months of onset. Throughout the cerebral white matter and to a lesser extent in the brainstem, there are foci of coagulation necrosis of varying size and severity. In the smaller lesions, a perivascular topography of tissue disintegration is evident. The pathogenesis of this disorder is unclear. Radiation injury
seems to be the most important factor, coupled with the age of the patient (most are under 5 years old). It has been speculated that radiation breaks down the blood-brain barrier, allowing methotrexate to injure myelin. Lack of circulation in the necrotic zones prevents the usual liquefaction and eventual cavitation. In this respect it resembles radiation necrosis.

**Involvement of the Nervous System in Systemic Lymphoma**

Extradural compression of the spinal cord or cauda equina is the most common neurologic complication of all types of lymphoma, the result of extension from vertebrae or paravertebral lymph nodes. Treatment is radiation or, if a tissue diagnosis is lacking, surgical decompression. Systemic lymphoma rarely metastasizes to the brain. In a review of more than 100 autopsies at the Mallory Institute of Pathology; our colleague R. D. Adams observed only a half-dozen instances where patients with lymphomas had deposits of tumor cells in the brain, and in none of these cases were they from multiple myeloma or plasmacytoma (Sparling et al). In the series of Levitt et al, comprising 592 patients with non-Hodgkin lymphoma, there were only 8 with intracerebral metastases. Much more common is meningeal dissemination of non-Hodgkin lymphoma, the clinical and CSF pictures being similar to those of meningeal leukemia and carcinoma described above. In the rare cases of meningeal involvement with Hodgkin lymphoma, there may be an eosinophilic pleocytosis. Leptomeningeal dissemination occurs almost exclusively in small-cell, high-grade lymphomas with diffuse (rather than nodular) changes in the lymph nodes. Cranial nerve palsies are common, with a predilection for the eighth nerve; the cauda equina is involved eventually in most cases. The optimal treatment has not yet been ascertained. Radiotherapy and systemic and intraventricular chemotherapy have all met with some degree of success.

**Intravascular Lymphoma (Malignant Angioendotheliomatosis, Angiotropic or Angioblastic Lymphoma, and Lymphomatoid Granulomatosis)**

These related conditions are presented here with other forms of lymphoma, although their clinical behavior is more in keeping with a vasculitic process and the diagnosis is difficult. Although considered rare, we encounter a new case yearly on our services. The nomenclature is confusing and the original term, *lymphomatoid granulomatosis*, is not universally accepted as equivalent to the more recently elucidated process of intravascular lymphoma; it is more accurate to consider it a prelymphomatous process. As originally described by Liebow and colleagues, lymphomatoid granulomatosis is a systemic disease with prominent pulmonary, dermal, and lymph node changes and, in approximately 30 percent of cases, with involvement of the CNS. In a small proportion of cases, the changes are confined to the nervous system. According to Katzenstein and associates, a systemic malignant lymphoma develops in about 12 percent of such patients, but others have noted this transformation in a considerably higher number.

The *angioblastic or intravascular lymphoma*, on the other hand, is regarded as a multifocal neoplasm of large anaplastic lymphocytes that infiltrate the walls of blood vessels and surrounding areas (Sheibani et al) or grow intravascularly and cause occlusion of small and moderate-sized vessels; hence the several alternative designations for the same pathologic process. The disease can be distinguished from brain lymphoma, which is typically “angiocentric,” meaning centered around vessels, but brain lymphoma does not selectively invade and occlude vascular structures. In the brain and spinal cord there are lesions of various sizes that represent the combined effects of occlusion of small vessels and concentric infiltration of the adjacent tissue by neoplastic cells. In half of the cases, meningeal vessels are involved and the neoplastic cells have incited an inflammatory response that can be detected in the spinal fluid, although malignant cells are not found in the fluid. In a few cases, the peripheral nerves, or more particularly the roots, have also been involved by the neoplasm, and we have seen two cases with a flaccid paraplegia on this basis.

Although the lymphoid origin of the anaplastic cells is now clear, not all of them are T cells, as was at one time believed; an equal number have the features of B cells. Moreover, in some cases as in primary CNS lymphoma, portions of the genome of the Epstein-Barr virus (EBV) have been isolated from the malignant B cells within the pleocellular infiltrates. For these reasons it has been proposed that the disorder represents an EBV-induced proliferation of B cells with a prominent inflammatory T-cell reaction (Guinee et al).

Because of the inconsistent location and size of the nervous system lesions, there is no uniform syndrome, but the disease should be suspected in patients with a subacute encephalopathy and indications of focal brain and spinal cord or nerve root lesions. Headache is a prominent early component in some cases. One of our patients had intermittent seizures 3 months before confusion and progressive encephalopathy. The variety of clinical presentations is emphasized in the reviews of 8 cases by Beristain and Azzarelli and the article by Glass and associates. All had focal cerebral signs, 7 had dementia, 5 had seizures, and 2 had myelopathy. Some of our own cases, as mentioned above, have also had a flaccid paraplegia due to infiltration of the cauda roots; this peripheral involvement has been commented on by other authors. Only a few patients will have nodular or multiple infiltrative pulmonary lesions, skin lesions, or adenopathy; almost all of our cases were restricted to the brain and spinal cord, but other reports suggest systemic disease in a high proportion.

MRI shows multiple nodular or variegate abnormalities in T2-weighted images throughout the white matter of the brain; most lesions are enhanced by gadolinium. In one of the cases we studied there were numerous hemorrhagic lesions. Definitive diagnosis is possible only through a biopsy of radiographically involved lung or nervous tissue that includes numerous intrinsic blood vessels. A helpful diagnostic feature is the presence of antibodies to nuclear cytoplasmic antigens (c-ANCA), which are present in some cases, as they are in a number of other vasculitic and granulomatous processes. A few of our own patients have also had adrenal or renal enlargement; presumably due to infiltration of the vessels of these organs by the neoplasm. The spinal fluid has a variable lymphocytic pleocytosis and protein elevation, but malignant cells are not found. The sedimentation rate and serum LDH are said to be elevated in most patients, but this has not been so in our experience.

Like demyelinating and lymphomatous lesions, these abnormalities may recede temporarily in response to treatment with corticosteroids, and some clinical improvement occurs. The course tends to be indolent and relapsing over months or years, although one of our patients died within weeks despite treatment. In a few cases, whole-brain irradiation has been successful in prolonging survival, but the outlook in most instances is poor.

An uncertain number of these patients have AIDS (none in our group). The illness must be distinguished from multiple sclerosis, brain lymphoma, gliomatosis cerebri, and a process that simulates it closely, sarcoidosis (which produces brain and lung lesions) as well as from the cerebral vasculitides and Behçet disease,
but intravascular lymphoma is generally more rapidly progressive than most of these conditions.

**Sarcomas of the Brain** These are malignant tumors composed of cells derived from connective tissue elements (fibroblasts, rhabdomyocytes, lipocytes, osteoblasts, smooth muscle cells). They take their names from their histogenetic derivation—namely, fibrosarcoma, rhabdomyosarcoma, osteogenic sarcoma, chondrosarcoma—and sometimes from the tissue of which the cells are a part, such as adventitial sarcomas and hemangiopericytoma.

All these tumors are rare. They constitute from 1 to 3 percent of intracranial tumors, depending on how wide a range of neoplasms one chooses to include in this group (see below). Occasionally one or more cerebral deposits of these types of tumors will occur as a metastasis from a sarcoma in another organ. Others are primary in the cranial cavity and exhibit as one of their unique properties a tendency to metastasize to nonneural tissues—a decidedly rare occurrence with primary glial tumors. It is a disturbing fact that a few sarcomas have developed 5 to 10 years after irradiation or, in one instance among 3000 patients of which we are aware, after proton beam irradiation of the brain. Fibrosarcomas have occurred after radiation of pituitary adenomas and osteogenic sarcoma after other types of radiation, all localized to bone or membranes. Our experience with hemangiopericytoma has been limited to two intracranial lesions that simulated meningiomas and two others that arose in the high cervical spinal cord and caused subacute quadriparesis initially misdiagnosed as a polyneuropathy.

A number of other cerebral tumors, described in the literature as sarcomas, are probably tumors of other types. The rapidly growing, highly malignant “monstrocellular sarcoma” of Zülch or “giant-cell fibrosarcoma” of Kernohan and Uihlein, so named for their multinucleated giant cells, have been reinterpreted by Rubinstein as a form of giant-cell glioblastoma or mixed glioblastoma and fibrosarcoma. The “hemangiopericytoma of the leptomeninges,” also classified by Kernohan and Uihlein as a form of cerebral sarcoma, is considered by Rubinstein to be a variant of the angioblastic meningioma of Bailey and Cushing.

**Patients Who Present Primarily with Signs of Increased Intracranial Pressure**

Upon first presentation, a number of patients show the characteristic symptoms and signs of increased intracranial pressure: periodic bifrontal and bioccipital headaches that awaken the patient during the night or are present upon awakening, projectile vomiting, mental torpor, unsteady gait, sphincteric incontinence, and papilledema. Most of these symptoms and the increased ICP are the result of hydrocephalus.

The diagnostic problem is resolved by CT or MRI, which should be obtained in all patients with symptoms of increased intracranial pressure with or without focal signs. The tumors most likely to present in this way are medulloblastoma, ependymoma of the fourth ventricle, hemangioblastoma of the cerebellum, pinealoma, colloid cyst of the third ventricle, and less often, craniopharyngioma or a high spinal cord tumor. In addition, with some of the cerebellar gliomas discussed in the preceding section, increased intracranial pressure may occasionally precede focal cerebral signs.

**Medulloblastoma, Neuroblastoma, and Retinoblastoma**

**Medulloblastoma** The medulloblastoma is a rapidly growing embryonic tumor that arises in the posterior part of the cerebellar vermis and neuroepithelial roof of the fourth ventricle in children. It accounts for 20 percent of childhood brain tumors. Rarely, it presents elsewhere in the cerebellum or other parts of the brain in adults (Peterson and Walker).

The origin of this tumor remained in doubt for a long time. Bailey and Cushing introduced the name medulloblastoma, although medulloblasts have never been identified in the fetal or adult human brain; nevertheless the term is retained for no reason other than its familiarity. The current view of the tumor is that it originates from “stem cells” that have been prevented from maturing and differentiating to their normal growth-arrested state. They retain their capacity to divide ad infinitum. The tumor may differentiate uni- or pluripotentially, varying from case to case. This accounts for the recognized histologic variants, ranging from the undifferentiated medulloblastoma to medulloblastoma with glial, neuronal, or even myoblastic components. Rosette formation, highly characteristic of the below-described neuroblastoma is seen in half of medulloblastoma cases. Molecular genetic qualities relate the medulloblastoma to retinoblastomas and certain pineal cell tumors and, rarely, to certain autosomal dominant diseases such as nevoid basal cell carcinoma. The most common histologic variant, recognized by Hortega in his classic work on the histology of brain tumors, is the “isomorphic glioblastoma,” from which both astrocytes and oligodendrocytes are derived.

Studies of cell lines from human medulloblastomas reveal a loss of genetic information on the distal part of chromosome 17 distal to the p53 region. Schmidek has proposed that this accounts for the neoplastic transformation of cerebellar stem cells, at various stages of their differentiation, into tumor cells. It is also notable that medulloblastomas are encountered in Gorlin syndrome, caused by mutations in the gene encoding “patched,” the receptor for sonic hedgehog ligand, and in Turcot syndrome, due to mutations in DNA repair genes (Luis et al). Another line of research has strongly implicated the JC virus, the same agent that causes progressive multifocal leukoencephalopathy (Chap. 33). Genomic sequences from this virus have been found in 72 percent of tumors in some series (Khalili et al), and an experimental transgenic model in which the JC protein is expressed is characterized by a cerebellar tumor that resembles the medulloblastoma. Neuroblastomas differ from medulloblastomas when analyzed for genetic markers, as indicated below.

The majority of the patients are children 4 to 8 years of age, and males outnumber females 3:2 or 3:1 in the many reported series. As a rule, symptoms have been present for 1 to 5 months before the diagnosis is made. The clinical picture is distinctive and derives from secondary hydrocephalus and raised intracranial pressure as a result of blockage of the fourth ventricle. Typically, the child becomes listless, vomits repeatedly, and has a morning headache. The first diagnosis that suggests itself may be gastrointestinal disease or abdominal migraine. Soon, however, a stumbling gait, frequent falls, and diplopia as well as strabismus lead to a neurologic examination and the discovery of papilledema or sixth nerve palsies. Papilledema is present in almost all children with small proportion of patients by the time they come to the attention of the neurologist. However, when the tumor is located in the lateral cerebellum or in the cerebrum, as it usually is in adults, signs of raised intracranial pressure may be delayed. Dizziness (positional) and nystagmus are frequent. A small proportion of these children have a slight sensory loss on one side of the face and a mild facial weakness. Head tilt, the occiput being tilted back and away from the side of the tumor, indicates a developing cerebellar-foraminal herniation. Rarely, signs of spinal root and subarachnoid metastases precede cerebellar
Ependymoma and Papilloma of the Fourth Ventricle  
Ependymomas, as pointed out earlier in this chapter, arise from the lining cells in the walls of the ventricles. About 70 percent of them originate in the fourth ventricle, according to Fokes and Earle (Fig. 31-12). Postmortem, some of these tumors, if small, are found protruding into the fourth ventricle, never having produced local symptoms. Whereas the supratentorial ependymoma occurs at all ages, fourth ventricular ependymomas appear mostly in childhood. In the large series of Fokes and Earle (83 cases), 33 developed in the first decade, 6 in the second, and 44 after the age of 20 years. Males have been affected almost twice as often as females.

Ependymomas usually arise from the floor of the fourth ventricle and extend through the foramina of Luschka and Magendie. They may later invade the medulla. These tumors produce a clinical syndrome much like that of the medulloblastoma except for their more protracted course and lack of early cerebellar signs. The histologic features of this tumor have been described earlier in this chapter. The degree of anaplastic change varies and has prognostic significance. The most anaplastic form is the ependymoblastoma, a highly aggressive tumor that falls within the spectrum of primitive neuroectodermal tumors (see below).

Symptoms may be present for 1 or 2 years before diagnosis and operation. About two-thirds of the patients come to notice because of increased intracranial pressure; in the remainder, vomiting, difficulty in swallowing, paresthesias of the extremities, abdominal pain, vertigo, and neck flexion or head tilt are prominent manifestations. Some patients with impending cerebellar-tonsillar hernia-
Papillomas of the choroid plexus are about one-fifth as frequent as ependymomas. They arise mainly in the lateral and fourth ventricles, occasionally in the third. Two authoritative studies (Lawrence et al; Matson and Crofton) give the ratios of lateral/third/fourth ventricular locations as 50:10:40. The tumor, which takes the form of a giant choroid plexus, has as its cellular element the cuboidal epithelium of the plexus, which is closely related embryologically to the ependyma. An oncogene T (tumor) antigen of the SV40 virus is possibly involved in tumor induction (see Schmidek). Essentially these are tumors of childhood. Fully 50 percent cause symptoms in the first year of life and 75 percent in the first decade. In the younger patients, hydrocephalus is usually the presenting syndrome, sometimes aggravated acutely by hemorrhage; there may be papilledema, an unusual finding in a hydrocephalic infant with enlarging head. Headaches, lethargy, stupor, spastic weakness of the legs, unsteadiness of gait, and diplopia are more frequent in the older child. Sometimes patients present with a syndrome of the cerebellopontine angle (see further on), where the tumor arises from choroid plexus and projects into the lateral recess of the fourth ventricle. One consequence of the tumor is thought to be increased CSF formation, which contributes to the hydrocephalus. Some of the tumors acquire more malignant attributes (mitoses, atypia of nuclei) and invade surrounding brain. They have the appearance of a carcinoma and may be mistaken for an epithelial metastasis from an extracranial site.

Treatment by surgical excision is usually curative, but palliative ventricular shunting may be needed first if the patient’s condition does not permit surgery. The prognosis of the rare choroid plexus carcinomas is poor.

**Primitive Neuroectodermal Tumors (PNETs)** This term was introduced by Hart and Earle in 1973 to describe tumors that have the histologic features of medulloblastoma but occur supratentorially. Various poorly differentiated or embryonal tumors of infancy and childhood were included in this group: medulloblastoma, neuroblastoma, retinoblastoma, ependymoblastoma, and pineoblastoma (described further on). Subsequent authors have broadened the category of PNETs to include all CNS neoplasms of neuroectodermal origin. With the advent of immunohistochemical techniques, many of these poorly differentiated neoplasms of infancy came to be recognized as small-cell gliomas (Friede et al); others, after ultrastructural study, could be classified as other types of primitive neoplasms. To some pathologists, the term primitive neuroectodermal tumors has a certain appeal but has added little to our understanding of their undifferentiated embryonal origin. In practical terms, the prognosis and treatment of all these tumors is much the same, regardless of what they are called (see Duffner and colleagues). As described earlier, certain patterns of gene expression are now used to distinguish this group of tumors from histologically similar medulloblastomas.

**Hemangioblastoma of the Cerebellum** This tumor is referred to most often in connection with von Hippel-Lindau disease (page 873). Dizziness, ataxia of gait or of the limbs on one side, symptoms and signs of increased intracranial pressure from compression of the fourth ventricle, and in some instances an associated retinal angioma or hepatic and pancreatic cysts (disclosed by CT or MRI) constitute the syndrome. There is a tendency later for the development of malignant renal or adrenal tumors. Many patients have polycythemia due to elaboration of an erythropoietic factor by the tumor.
The age of onset is usually between 15 and 50 years. Blacks, whites, and Asians are equally affected. Dominant inheritance of von Hippel-Lindau disease is well known. Seizinger and coworkers, in cases associated with renal cell carcinoma and pheochromocytoma, have localized a defect in a tumor suppressor gene (termed VHL) on chromosome 3p (see Chap. 38).

The diagnosis can be deduced from the appearance on CT or MRI of a cerebellar cyst containing an enhancing nodular lesion on its wall. Often the associated retinal hemangioma will be disclosed by the same imaging procedure. The angiographic picture is also characteristic: a tightly packed cluster of small vessels forming a mass 1.0 to 2.0 cm in diameter (Fig. 31-13). Craniotomy with opening of the cerebellar cyst and excision of the mural hemangioblastomatous nodule is usually curative, but there is a high rate of recurrence if the entire tumor, including the nodule, is not completely removed. In the series of Boughey and colleagues, the lesion was successfully excised in 80 percent of patients. Fifteen percent of patients, who had only partial resection of an isolated cerebellar lesion, developed recurrent tumors. More recently, several groups have used endovascular embolization of the vascular nodule prior to surgery, but it is not clear if this reduces the incidence of recurrence. Treatment with small doses of focused radiation is also being undertaken but must be considered experimental until more results are available.

Hemangioblastomas of the spinal cord are frequently associated with a syringomyelic lesion (greater than 70 percent of cases); such lesions may be multiple and are located mainly in the posterior columns. A retinal hemangioblastoma may be the initial finding and leads to blindness if not treated by laser. The children of a parent with a hemangioblastoma of the cerebellum should be examined regularly for an oculcar lesion and renal cell carcinoma. New lesions continue to be formed over a period of years while the patient is under observation.

**Figure 31-13.** Hemangioblastoma. MRI in the axial plane (left) shows the vascular tumor in the left cerebellar hemisphere. Selective left vertebral angiogram (right) defines a hypervascular nodule with dilated draining veins.

### Pineal Tumors

There has been much uncertainty as to the proper classification of pineal tumors. Originally they were all thought to be composed of pineal cells, hence they were classified as true pinealomas, a term suggested by Krabbe. Globus and Silbert believed that these originated from embryonic pineal cells. But later Russell pointed out that some tumors in the pineal region are really atypical teratomas resembling the seminoma of the testicle. Four types of pineal tumor are now recognized—germinoma (atypical teratoma), pinealoma (pineocytoma and pineoblastoma), true teratoma with cellular derivatives of all three germ layers, and a glioma originating in astroglial cells of the pineal body.

The germinoma is a firm, discrete mass that usually reaches 3 to 4 cm in greatest diameter. It compresses the superior colliculi and sometimes the superior surface of the cerebellum and narrows the aqueduct of Sylvius. Often it extends anteriorly into the third ventricle and may then compress the hypothalamus. A germinoma may also arise in the floor of the third ventricle; this has been referred to as an ectopic pinealoma or suprasellar germinoma. Microscopically, these tumors are composed of large, spherical epithelial cells separated by a network of reticular connective tissue and containing many lymphocytes.

Of the four groups of pineal tumors, approximately 50 percent are germinomas. True teratomas and gliomas are relatively infrequent. Children, adolescents, and young adults—males more than females—are affected. Only rarely does one see a patient with a pineal tumor that has developed after the 30th year of life.

The pineocytoma and pineoblastoma reproduce the normal structure of the pineal gland. These tumors enlarge the gland, are locally invasive, and may extend into the third ventricle and seed along the neuraxis. Their growth characteristics resemble those of the germinoma. Cytologically, the pineocytoma is a moderately cellular tumor with none of the histologic attributes of anaplasia. The tumor cells tend to form circular arrangements, so-called...
pineocytomatous rosettes. Pineocytes may be impregnated by silver carbonate methods, and some contain the retinal S antigen of photoreceptor cells. Pineoblastomas are highly cellular and composed of small, undifferentiated cells bearing some resemblance to medulloblasts. The teratoma and dermoid and epidermoid cysts of the pineal have no special features—some are quite benign. The gliomas have the usual morphologic characteristics of an astrocytoma of varying degrees of malignancy. In some cases, the clinical syndrome of the several types of pineal tumors consists solely of symptoms and signs of increased intracranial pressure. Beyond this, the most characteristic localizing signs are an inability to look upward and slightly dilated pupils that react on accommodation but not to light (Parinaud syndrome). Sometimes ataxia of the limbs, choreic movements, or spastic weakness appears in the later stages of the illness. It is uncertain whether the ocular and motor signs are due to neoplastic compression of the brachia conjunctivae and other tegmental structures of the upper midbrain or to hydrocephalus (dilation of the posterior part of the third ventricle). Probably both mechanisms are operative. Precocious puberty occurs in males who harbor a germinoma. Although the pineal gland is the source of melatonin, sleep is not affected to an important degree in patients with these tumors, as discussed on page 482. Measurement of CSF or serum melatonin is useful mainly in the detection of tumor recurrence after surgical extirpation. The diagnosis is made by CT scanning and MRI (Fig. 31-14). The CSF may contain tumor cells and lymphocytes but may also be entirely normal.

**Treatment** These lesions were formerly judged to be inoperable. However, the use of the operating microscope now makes it possible to excise them by a supracerebellar or transtentorial approach. Operation for purposes of excision and histologic diagnosis is advised, because each type of pineal tumor must be managed differently. Moreover, one may occasionally find an arachnoidal cyst that needs only excision. The germinomas should be removed insofar as possible and the whole neuraxis irradiated. The use of chemotherapy in addition to or instead of cranial irradiation is still being evaluated (Allen). Several of our patients have survived more than 5 years after the removal of a pineal glioma.

**Other Germinomas, Gangliocytomas, and Mixed Neuronal-Glial Tumors** Malignant germ-cell tumors occurring in locations other than the pineal body are usually found in the suprasellar space and rarely in the roof of the third ventricle. Germinoma is the most common of this rare group of neoplasms, which also includes chorionic carcinoma, embryonal cell carcinoma, endodermal sinus tumors, and malignant teratomas. Certain biochemical markers of these tumors are of interest and of clinical utility, since they may be detected in samples of the blood and CSF. The beta subunit of human chorionic gonadotropin (hCG) is elaborated by chorionicarcoma, and alpha fetoprotein by chorionic carcinoma and immature teratomas. Typical germinomas have shown little elevation of either. Most often these markers indicate the presence of complex mixed germ-cell tumors.

Gangliogliomas and mixed neuronal-glial tumors are special tumor types, more frequent in the young and of variable but usually low-grade malignancy. They are composed both of differentiated glial cells, usually astrocytes, and of neurons in various degrees of differentiation. The latter, which may resemble glial cells, can be identified by Nissl stains, silver stains, and immunohistochemical reactions for cytoskeletal proteins. Some of these developmental tumors are difficult to separate from hamartomas or the ventricular tubers of tuberous sclerosis.

Figure 31-14. Pinealoma. MRI in the sagittal plane (above) demonstrates the tumor (large arrow), which compresses the superior cerebellum (smaller arrow) and the aqueduct (long-stemmed arrow). An axial cut (below) shows the tumor (straight arrow) and evidence of hydrocephalus (curved arrow), the result of aqueductal compression. (Reproduced by permission from Bisese JH: Cranial MRI. New York, McGraw-Hill, 1991.)

The best-known type in this group is the gangliocytoma, one form of which is the dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease). This is a slowly evolving lesion that forms a mass in the cerebellum; it is composed of granule, Purkinje, and glial cells. Reproduced therein, in a disorganized fashion, is the architecture of the cerebellum. The importance of distinguishing this disease from other cerebellar tumors is its lack of growth potential and favorable prognosis. It should be excised if symptomatic.

Other forms of gangliogliomas include the desmophilic infantile ganglioglioma, some of the xanthoastrocytomas, and the dysriboplastic neuroepitheliomas. Often they lie near the ventricles, and they may induce hydrocephalus. Many of these tumors are rare and affect children mostly; therefore they are not discussed further here. Good descriptions are to be found in the monographs of Rus-
Colloid (Paraphysial) Cyst and Other Tumors of the Third Ventricle  The most important of these is the colloid tumor, which is probably congenital, presents clinically at all ages but may become evident only in adult life, when it gives rise to symptoms of increased intracranial pressure and sometimes to focal cerebral or cerebellar signs, simulating intracranial neoplasm. Seizures may occur but are not characteristic; we have seen only one instance. In infants and young children, macrocrania and extensive unilateral transillumination are characteristic features. Usually these cysts overlie the sylvian fissure; occasionally they are interhemispheric under the frontal lobes or lie in the pineal region or under the cerebellum. They may attain a large size, to the point of enlarging the middle fossa and elevating the lesser wing of the sphenoid, but they do not communicate with the ventricle. Rarely, one of these cysts may cover the entire surface of both cerebral hemispheres and create a so-called external hydrocephalus (page 533).

The cysts are readily recognized (often accidentally) on the nonenhanced CT scan or MRI, showing a circumscribed tissue defect filled with fluid that has the density of CSF (Gandy and Heier). If these cysts are completely asymptomatic, they should be left alone; if symptomatic, additional (MRI) studies are indicated, so as not to overlook a chronic subdural hematoma, which is often associated and may not be visualized on the unenhanced CT scan. Suprasellar arachnoid cysts are discussed further on (page 577).

The treatment of enlarging and symptomatic cysts is marsupialization or, less preferably, by shunting from the cyst to the subarachnoid space.

Patients Who Present with Specific Intracranial Tumor Syndromes  In this group of tumors, symptoms and signs of general cerebral impairment and increased pressure occur late or not at all. Instead, special syndromes referable to particular intracranial loci arise and progress slowly. One arrives at the correct diagnosis by localizing the lesion accurately from the neurologic findings and by reasoning that the etiology must be neoplastic because of an afebrile and steady progressive nature. Investigation by CT, MRI, and other special studies will usually confirm the clinical impression.

The tumors that most often produce these unique intracranial syndromes are acoustic neuroma and other tumors of the cerebellopontine angle, craniopharyngioma, pituitary adenomas and various nonneoplastic enlargements of the sella, meningiomas of the sphenoid ridge and olfactory groove, glioma of the optic nerve and chiasm, pontine glioma, chordoma and chondrosarcoma, glomus arteriovenous cysts. This lesion, which is probably congenital, presents clinically at all ages but may become evident only in adult life, when it gives rise to symptoms of increased intracranial pressure and sometimes to focal cerebral or cerebellar signs, simulating intracranial neoplasm. Seizures may occur but are not characteristic; we have seen only one instance. In infants and young children, macrocrania and extensive unilateral transillumination are characteristic features. Usually these cysts overlie the sylvian fissure; occasionally they are interhemispheric under the frontal lobes or lie in the pineal region or under the cerebellum. They may attain a large size, to the point of enlarging the middle fossa and elevating the lesser wing of the sphenoid, but they do not communicate with the ventricle. Rarely, one of these cysts may cover the entire surface of both cerebral hemispheres and create a so-called external hydrocephalus (page 533).

The cysts are readily recognized (often accidentally) on the nonenhanced CT scan or MRI, showing a circumscribed tissue defect filled with fluid that has the density of CSF (Gandy and Heier). If these cysts are completely asymptomatic, they should be left alone; if symptomatic, additional (MRI) studies are indicated, so as not to overlook a chronic subdural hematoma, which is often associated and may not be visualized on the unenhanced CT scan. Suprasellar arachnoid cysts are discussed further on (page 577).

The treatment of enlarging and symptomatic cysts is marsupialization or, less preferably, by shunting from the cyst to the subarachnoid space.

Suprasellar arachnoid cysts are discussed further on (page 577).

The treatment of enlarging and symptomatic cysts is marsupialization or, less preferably, by shunting from the cyst to the subarachnoid space.
jugulare and carotid body tumors, as well as a number of other erosive tumors at the base of the skull.

Acoustic Neuroma (Vestibular Schwannoma)  This tumor was first described as a pathologic entity by Sandifort in 1777, first diagnosed clinically by Oppenheim in 1890, and first recognized as a surgically treatable disease in the early 1900s. Cushing’s monograph (1917) was a milestone, and the papers of House and Hitselberger and of Ojemann and colleagues provide excellent descriptions of the modern diagnostic tests and surgical treatment as well as comprehensive bibliographies.

Approximately 3000 new cases of acoustic neuroma are diagnosed each year in the United States (incidence rate of 1 per 100,000 per year). The tumor occurs occasionally as part of von Recklinghausen neurofibromatosis, in which case it takes one of two forms. In classic von Recklinghausen disease (peripheral or type 1 neurofibromatosis, see page 869), a schwannoma may sporadically involve the eighth nerve, usually in adult life, but it may involve any other cranial nerve (particularly trigeminal) or spinal nerve root. Rarely if ever do bilateral acoustic neuromas occur in this form of the disease. However, bilateral acoustic neuromas are the hallmark of the genetically distinct neurofibromatosis type 2, in which they practically always occur before the age of 21 and show a strong (autosomal dominant) heredity (Fig. 31-16). Schwannomas are distinguished from neurofibromas (composed of both Schwann cells and fibroblasts) found in peripheral nerves of type 1 von Recklinghausen disease. A small percentage of neurofibromas become malignant, a phenomenon that is highly unusual in schwannomas.

In this context, it should be stated that there is a form of familial schwannomatosis, characterized by multiple schwannomas without vestibular tumors, that maps genetically to chromosome 22 but is distinct from NF2. The primary gene defect in this familial schwannomatosis has not been defined (MacCollin et al).

The usual acoustic neuroma in adults presents as a solitary tumor. Being a schwannoma, it originates in nerve. The examination of small tumors reveals that they practically always arise from the vestibular division of the eighth nerve, just within the internal auditory canal (Fig. 31-17). As the eighth nerve schwannoma grows, it extends into the posterior fossa to occupy the angle between the cerebellum and pons (cerebellopontine angle). In this lateral position it is so situated as to compress the seventh, fifth, and less often the ninth and tenth cranial nerves, which are implicated in various combinations. Later it displaces and compresses the pons and lateral medulla and obstructs the CSF circulation; very rarely, it is a source of subarachnoid hemorrhage.
Certain biologic data assume clinical importance. The highest incidence is in the fifth and sixth decades, and the sexes are equally affected. Familial occurrence is a mark, usually, of von Recklinghausen disease.

The earliest symptom reported by the 46 patients in the series of Ojemann and coworkers was loss of hearing (33 of 46 patients); headache (4 patients); disturbed sense of balance (3 patients); unsteadiness of gait (3 patients); or facial pain, tinnitus, and facial weakness—each in a single case. Some patients sought medical advice soon after the appearance of the initial symptom, some later, after other symptoms had occurred. Usually, by the time of the first neurologic examination, the clinical picture was quite complex. One-third of the patients were troubled by vertigo associated with nausea, vomiting, and pressure in the ear. The vertiginous symptoms differed from those of Ménière disease in that discrete attacks separated by periods of normalcy were rare. The vertigo coincided more or less with hearing loss and tinnitus (most often a unilateral high-pitched ringing, sometimes a machinery-like roaring or hissing sound, like that of a steam kettle). By then, many of the patients were also complaining of unsteadiness, especially on rapid changes of position (e.g., in turning), and this may have interfered with work and other activities. Some of our patients ignored their deafness for many months or years; often the first indication of the tumor in such patients has been a shift to the unaccustomed ear (usually right to left) in the use of the telephone. Others neglected these symptoms to a point where they presented with impaired mentation, imbalance, and sphincteric incontinence due to brainstem compression and secondary hydrocephalus.

The neurologic findings at the time of examination in the series mentioned above were as follows: eighth nerve involvement (auditory and vestibular) in 45 of 46, facial weakness including disturbance of taste (26 patients), sensory loss over the face (26 patients), gait abnormality (19 patients), and unilateral ataxia of the limbs (9 patients). Inequality of reflexes and 11th and 12th nerve palsies were present in only a few patients. Signs of increased intracranial pressure appear late and have been present in fewer than 25 percent of our patients. These findings are comparable to those reported by House and Hitselberger and by Harner and Laws.

The contrast-enhanced CT scan will detect practically all acoustic neuromas that are larger than 2.0 cm in diameter and project further than 1.5 cm into the cerebellopontine angle. Much smaller intracanalicular tumors (i.e., restricted to the acoustic canal in the petrous bone) can be detected reliably by MRI with gadolinium enhancement (Fig. 31-17), a procedure that in general is the most useful in determining size and anatomic relationships. Audiologic and vestibular evaluation includes the various tests described in Chap. 15, the brainstem auditory evoked response probably being the most sensitive. In combination, they permit localization of the deafness and vestibular disturbance to the cochlear and vestibular nerves rather than to their end organs. The CSF protein is raised in two-thirds of the patients (over 100 mg/dl in one-third); a clinically inevident acoustic schwannoma is one of the causes of an unexpectedly high CSF protein when a lumbar puncture is performed for other reasons.

**Treatment** The preferred treatment in most cases has been surgical excision. Most neurosurgeons who have had a large experience with these tumors favor a microsurgical suboccipital transmeatal operation (Martuza and Ojemann). The facial nerve can usually be preserved by intraoperative monitoring of brainstem auditory responses and facial nerve electromyography (EMG); in experienced hands, hearing can be preserved in approximately one-third of patients with tumors smaller than 2.5 cm in diameter. If no attempt is to be made to save hearing, small tumors can be removed safely by the translabyrinthine approach. An alternative to surgery is focused gamma or proton radiation, which controls the growth of many of the smaller tumors. In a large series of patients treated with radiosurgery, facial motor and sensory functions were preserved in three-quarters of cases and, after 28 months of observation, no new neurologic deficits were detected (Kondziolka et al). This approach is favored in older patients with few symptoms but is being adopted increasingly for others. The rates of hearing loss and facial numbness and weakness are comparable or lower than with surgery but the follow-up period in most series is less than 5 years (Flickinger et al). Focused radiation with the gamma knife or linear accelerator also appears to be preferable to surgery in cases of recurrent tumor.

**Other Tumors of the Cerebellopontine Angle Region** Neurinoma or schwannoma of the trigeminal (gasserian) ganglion or neighboring cranial nerves and meningioma of the cerebellopontine angle may in some instances be indistinguishable from an acoustic neuroma. Fifth nerve tumors should always be considered if deafness, tinnitus, and lack of response to caloric stimulation (“dead labyrinth”) are not the initial symptoms of a cerebellopontine angle syndrome. A true cholesteatoma (epidermoid cyst) is a relatively rare tumor that is most often located in the cerebellopontine angle, where it may simulate an acoustic neuroma but usually causes more severe facial weakness. Spillage of the contents of the cyst may produce an intense chemical meningitis. Other disorders that enter into the differential diagnosis are glomus jugulare tumor (see below), metastatic cancer, syphilitic meningitis, arachnoid cyst, vascular malformations, and epidural plasmacytoma of the petrous bone. All these disorders may produce a cerebellopontine angle syndrome, but they are more likely to cause only unilateral lower cranial nerve palsies and their temporal course tends to differ from that of an acoustic neuroma. Occasionally, a tumor that originates in the pons or in the fourth ventricle (ependymoma, astrocytoma, papilloma, medulloblastoma) or a nasopharyngeal carcinoma may present as a cerebellopontine angle syndrome.

**Cranioopharyngioma (Suprasellar Epidermoid Cyst, Rathke’s Pouch or Hypophysial Duct Tumor, Adamantinoma)** This is a histologically benign epithelial tumor, generally assumed to originate from cell rests (remnants of Rathke’s pouch) at the junction of the infundibular stem and pituitary. By the time the tumor has attained a diameter of 3 to 4 cm, it is almost always cystic and partly calcified. Usually it lies above the sella turcica, depressing the optic chiasm and extending up into the third ventricle. Less often it is subdiaphragmatic, i.e., within the sella, where it compresses the pituitary body and erodes one part of the wall of the sella or a clinoid process; seldom does it balloon the sella like a pituitary adenoma. Large tumors may obstruct the flow of CSF. The tumor is oval, round, or linear and has a smooth surface. The wall of the cyst and the solid parts of the tumor consist of cords and whorls of epithelial cells (often with intercellular bridges and keratinohyalin) separated by a loose network of stellate cells. If there are bridges between tumor cells, which have an epithelial origin, the tumor is classed as an adamantinoma. The cyst contains dark albuminous fluid, cholesterol crystals, and calcium deposits; the calcium can be seen in plain films or CT scans of the suprasellar region in 70 to 80 percent of cases. The sella beneath the tumor tends to be flattened and enlarged. The majority of the patients are...
children, but the tumor is not infrequent in adults, and we have encountered patients up to 60 years of age.

The presenting syndrome may be one of increased intracranial pressure, but more often it takes the form of a combined pituitary-hypothalamic-chiasmal derangement. The symptoms are often subtle and of long standing. In children, visual loss and diabetes insipidus are the most frequent findings, followed by adipsody, delayed physical and mental development (Froehlich or Lorain syndrome—see page 486), headaches, and vomiting. The visual disorder takes the form of dim vision, chiasmal field defects, optic atrophy, or papilledema, as emphasized long ago by Kennedy and Smith. In adults, waning libido, amenorrhea, slight spastic weakness of one or both legs, headache without papilledema, failing vision, and mental dullness and confusion are the usual manifestations. One of the most remarkable cases in our experience was a middle-aged nurse who became distractible and ineffective at work and was thought for many months to be simply depressed. Often it is observed that drowsiness, ocular palsies, diabetes insipidus, and disturbance of temperature regulation (indicating hypothalamic involvement) occur later. Spontaneous rupture of the cystic lesion can incite a severe aseptic meningitis, at times with depressed glucose in the CSF.

In the differential diagnosis of the several craniopharyngioma syndromes, a careful clinical analysis is more informative than laboratory procedures. Among the latter, MRI is likely to give the most useful information. Often, because of the cholesterol content, the tumor gives an increased signal on T1-weighted images. Usually, the cyst itself is isointense, like CSF, but occasionally it may give a decreased T2 signal.

**Treatment** Modern microsurgical techniques, reinforced by corticosteroid therapy before and after surgery and careful control of temperature and water balance postoperatively permit successful excision of all or part of the tumor in the majority of cases. While smaller tumors can be removed by a transsphenoidal approach, attempts at total removal require craniotomy and remain a challenge because of frequent adherence of the mass to surrounding structures (Fahlsbusch et al.). Partial removal practically assures recurrence of the tumor mass, usually within 3 years, and the surgical risks of reoperation are considerable (10 percent mortality in large series). In 21 of our 35 patients, only partial removal was possible; of these, 8 died, most in the first postoperative year. Stereotaxic aspiration is sometimes a useful palliative procedure, as are focused radiation therapy and ventricular shunting in patients with solid, nonresectable tumors. Endocrine replacement is necessary for an indefinite time following tumor resection.

**Glomus Jugulare Tumor** This tumor is relatively rare but of particular interest nonetheless. It is a purplish red, highly vascular tumor composed of large epithelioid cells, arranged in an alveolar pattern and possessing an abundant capillary network. The tumor is thought to be derived from minute clusters of nonchromaffin paraganglioma cells (glomus bodies) found mainly in the adventitia of the dome of the jugular bulb (glomus jugulare) immediately below the floor of the middle ear but also in multiple other sites in and around the temporal bone. These clusters of cells are part of the chemoreceptor system that also includes the carotid, vagal, carotid, and aortic bodies.

The typical syndrome consists of partial deafness, facial palsy, dysphagia, and unilateral atrophy of the tongue combined with a vascular polyp in the external auditory meatus and a palpable mass below and anterior to the mastoid eminence, occasionally with a bruit that may be audible to the patient (“self-audible bruit”). Other neurologic manifestations are phrenic nerve palsy, numbness of the face, a Horner syndrome, cerebellar ataxia, and temporal lobe epilepsy. The jugular foramen is eroded (visible in basilar skull films and CT) and the CSF protein may be elevated. Women are affected more than men, and the peak incidence is during middle adult life. The tumor grows slowly over a period of many years, sometimes 10 to 20 or more. Treatment has consisted of radical mastoidectomy and removal of as much tumor as possible, followed by radiation. The combined intracranial and extracranial two-stage operation has resulted in the cure of many cases (Gardner et al). A detailed account of this tumor will be found in the article by Kramer.

**Carotid Body Tumor (Paraganglioma)** This is a generally benign but potentially malignant tumor originating in a small aggregate of cells of neuroectodermal type. The normal carotid body is small (4 mm in greatest diameter and 10 mg in weight) and is located at the bifurcation of the common carotid artery. The cells are of uniform size, have an abundant cytoplasm, are rich in substance P, and are sensitive to changes in P02, Pco2, and pH (i.e., they are chemoreceptors, not to be confused with baroreceptors). The tumors that arise from these cells are identical in appearance with tumors of other chemoreceptor organs (paragangliomas). Interestingly, they are 12 times more frequent in individuals living at high altitudes.

Clinically the usual presentation is of a painless mass at the side of the neck below the angle of the jaw; thus it must be differentiated from the branchial cleft cyst, mixed tumor of the salivary gland, and carcinomas and aneurysms in this region. As the tumor grows (at an estimated rate of 2.0 cm in diameter every 5 years), it may implicate the sympathetic, glossopharyngeal, vagus, spinal accessory, and hypoglossal nerves (syndrome of the retroparotid space; see Chap. 47). Hearing loss, tinnitus, and vertigo are present in some cases. Tumors of the carotid body have been a source of transient ischemic attacks in 5 to 15 percent of the 600 or more reported cases. One of the most interesting presentations has been with sleep apnea, particularly with bilateral tumors (see below); respiratory depression as well as lability of blood pressure are common postoperative problems. Malignant transformation occurs in 5 percent of cases.

A similar paraganglioma of the vagus nerve has been reported; it occurs typically in the jugular or nodose ganglion but may arise anywhere along the course of the nerve. These tumors may also undergo malignant transformation, metastasize, or invade the base of the skull.

A carotid body tumor, separate in nature from the glomus jugulare tumor, has been seen in combination with von Recklinghausen neurofibromatosis. Familial cases are known, especially with bilateral carotid body tumors (about 5 percent of these tumors are bilateral). The treatment should be surgical excision with or without prior intravascular embolization; radiation therapy is not advised.

**Pituitary Adenomas** (See also page 486) Tumors arising in the anterior pituitary are of considerable interest to neurologists because they often cause visual and other symptoms related to involvement of structures bordering upon the sella turcica before an endocrine disorder becomes apparent. Pituitary tumors are age-linked; they become increasingly numerous with each decade; by the 80th year, small adenomas are found in more than 20 percent of pituitary glands. In some cases, an apparent stimulus to adenoma
Somatotropin (GH), thyrotropin (TSH), T4, TRH
Gonadotropin (FSH, LH, estradiol, testosterone, GnRH)
Adrenocorticotropic hormone (ACTH), beta-lipotropin, luteinizing hormone (LH), and follicle-stimulating hormone (FSH).

Key: FSH, follicle-stimulating hormone; LH, luteinizing hormone; GnRH, gonadotropin-releasing hormone; TRH, thyrotropin-releasing hormone; T4, thyroxine; TSH, thyroid-stimulating hormone; GH, growth hormone.
Males with prolactin-secreting tumors rarely have galactorrhea and usually present with a larger tumor and complaints such as headache, impotence, and visual abnormalities. In normal persons, the serum prolactin rises markedly in response to the administration of chlorpromazine or thyrotropin-releasing hormone (TRH); patients with a prolactin-secreting tumor fail to show such a response. With large tumors that compress normal pituitary tissue, thyroid and adrenal function will also be impaired. It should be noted that large, nonfunctioning pituitary adenomas also cause modest hyperprolactinemia by distorting the pituitary stalk and reducing dopamine delivery to prolactin-producing cells.

**Acromegaly** This disorder consists of acral growth and progranulism in combination with visceromegaly, headache, and several endocrine disorders (hypermetabolism, diabetes mellitus). The highly characteristic facial and bodily appearance, well known to all physicians, is due to an overproduction of growth hormone (GH) after puberty; prior to puberty, an oversecretion of GH leads to gigantism. In a small number of acromegalic patients, there is an excess secretion of both GH and prolactin, derived apparently from two distinct populations of tumor cells. The diagnosis of this disorder, which is often long delayed, is made on the basis of the characteristic clinical changes, the finding of elevated serum GH values (0.10 ng/mL), and the failure of the serum GH concentration to rise in response to the administration of glucose or TRH. The new growth hormone receptor antagonist pegvisomant has been introduced to reduce many of the manifestations of acromegaly (see the editorial by Ho).

**Cushing Disease** Described in 1932 by Cushing, this condition is only about one-fourth as frequent as acromegaly. A distinction is made between Cushing disease and Cushing syndrome, as indicated in Chap. 27. The former term is reserved for cases that are caused by the excessive secretion of pituitary ACTH, which in turn causes adrenal hyperplasia; the usual basis is a pituitary adenoma. Cushing syndrome refers to the effects of cortisol excess from any one of several sources—excessive administration of steroids (the most common cause), adenoma of the adrenal cortex, ACTH-producing bronchial carcinoma, and very rarely other carcinomas that produce ACTH. The clinical effects are the same in all of these disorders and include truncal obesity, hypertension, proximal muscle weakness, amenorrhea, hirsutism, abdominal striae, glycosuria, osteoporosis, and in some cases a characteristic mental disorder (page 978).

Although Cushing originally referred to the disease as pituitary basophilism and attributed it to a basophil adenoma, the pathologic change may consist only of hyperplasia of basophilic cells or of a nonbasophilic microadenoma. Seldom is the sella turcica enlarged: visual symptoms or signs due to involvement of the optic chiasm or nerves and extension to the cavernous sinus are therefore rare. The diagnosis of Cushing disease is made by demonstrating increased concentration of plasma and urinary cortisol; these levels are not suppressed by the administration of relatively small doses of dexamethasone (0.5 mg four times daily), but they are suppressed by high doses (8 mg daily). A low level of ACTH and a high level of cortisol in the blood, increased free cortisol in the urine, and nonsuppression of adrenal function after administration of high doses of dexamethasone are evidence of an adrenal source of the Cushing syndrome—usually a tumor and less often a microadenoma of the adrenal gland.

**Diagnosis of Pituitary Adenoma** This is virtually certain when a chiasmal syndrome is combined with an endocrine syndrome of either hypopituitary or hyperpituitary type. Laboratory data that are confirmatory of an endocrine disorder, as described above, and sometimes a ballooned sella turcica in plain films of the skull are occasionally found. Patients who are suspected of harboring a pituitary adenoma but in whom the plain films are normal should be examined by MRI. This procedure will visualize pituitary adenomas as small as 3 mm in diameter and show the relationship of the tumor to the optic chiasm. This also provides the means of following the tumor’s response to therapy (Fig. 31-18). It should be kept in mind that pituitary tissue normally enhances on CT and MRI, and small tumors are therefore revealed as nonenhancing nodules.

Tumors other than pituitary adenomas may sometimes expand the sella. Enlargement may be due to an intrasellar craniopharyngioma, carotid aneurysm, or cyst of the pituitary gland. Intrasellar epithelium-lined cysts are rare lesions. They originate from the apical extremity of Rathke’s pouch, which may persist as a cleft between the anterior and posterior lobes of the hypophysis. Rarer still are intrasellar cysts that have no epithelial lining and contain thick, dark brown fluid, the product of intermittent hemorrhages. Both types of intrasellar cyst may compress the pituitary gland and mimic the endocrine-suppressive effects of pituitary adenomas. Neoplasms originating in the nasopharynx or sinuses may invade the sella and pituitary gland, and sarcoid lesions at the base of the brain may do the same. Also, the pituitary gland (and the chiasm) may be the site of metastases, most of them from the lung and breast (Morita et al); they give rise to diabetes insipidus, pituitary...
insufficiency, or orbital pain and rarely may be the first indication of a systemic tumor.

Empty Sella Syndrome  More common than the aforementioned conditions is a nontumorous enlargement of the sella (“empty sella”). This results from a defect in the dural diaphragm, which may occur without obvious cause or with states of raised intracranial pressure, such as pseudotumor cerebri (page 538) or hydrocephalus, or may follow surgical excision of a pituitary adenoma or meningioma of the tuberculum sellae or pituitary apoplexy (see below). The arachnoid covering the diaphragm sellae will bulge downward through the dural defect, and the sella then enlarges gradually, due presumably to the pressure and pulsations of the CSF acting on its walls. In the process, the pituitary gland becomes flattened, sometimes to an extreme degree; however, the functions of the gland are usually unimpaired. Downward herniation of the optic chiasm occurs occasionally and may cause visual disturbances simulating those of a pituitary adenoma (Kaufman et al). As mentioned above, a bitemporal hemianopia with a normal-sized sella is usually due to a primary suprasellar lesion (saccular aneurysm of the distal carotid artery, meningoima, or craniopharyngioma).

Treatment This varies with the type and size of the tumor, the status of the endocrine and visual systems, and the age and childbearing plans of the patient. The administration of the dopamine agonist bromocriptine (which inhibits prolactin) in a beginning dosage of 0.5 to 1.25 mg daily (taken with food) may be the only therapy needed for small or even large prolactinomas and is a useful adjunct in the treatment of the amenorrhea-galactorrhea syndrome. The dose should be slowly increased by 2.5 mg or less every several days until a therapeutic response is obtained. Under the influence of bromocriptine, the tumor decreases in size within days, the prolactin level falls, and the visual field defect improves.

Some cases of acromegaly also respond to the administration of bromocriptine but even better to octreotide, an analogue of somatostatin. The initial dose of octreotide is 200 mg/day, increased in divided doses to 1600 mg by increments of 200 mg weekly. In Lamberts’ series of acromegaly patients, the growth hormone levels returned to normal and tumor size was reduced in 12 of 15 cases. Treatment with bromocriptine and octreotide must be continuous to prevent relapse. Newer slow-release somatostatin analogues and long-acting dopamine agonists such as cabergoline have been developed for use in patients who do not respond to the conventional agents (Colao and Lombardi).

If the patient is intolerant of bromocriptine (or, in the case of acromegaly, to octreotide and the newer drugs mentioned above), the treatment is surgical, using a transsphenoidal microsurgical approach, with an attempt at total removal of the tumor and preservation of normal pituitary function. Unfortunately, approximately 15 percent of GH-secreting tumors and prolactinomas will recur at 1 year. For this reason, incomplete removal or recurrence of the tumor (or tumors that are unresponsive to hormonal therapy) should be followed by radiation therapy.

Another alternative treatment for intrasellar tumors is proton beam radiation or some other form of stereotactic radiosurgery provided that vision is not being threatened and there is no other urgent need for surgery. These forms of radiation can be focused precisely on the tumor and will destroy it. Kjellberg and colleagues and Chapman, using proton beam radiation, treated over 1100 pituitary adenomas without a fatality and with few complications (Kliiman et al). A single brief exposure through intact skin and skull was all that was necessary. An endocrine deficit will follow in most instances and must be corrected by hormone replacement therapy.

Proton beam therapy is available in only very few centers worldwide, but equivalent methods (“gamma knife,” linear accelerator) are more accessible. The advantage of these radiotherapeutic methods is that tumor recurrence is rare. A disadvantage is that the radiation effect is obtained only after several months. Estrada and colleagues have also reported that external beam radiation therapy may be employed after unsuccessful transsphenoidal surgery for Cushing disease. After approximately 3.5 years, 83 percent of their patients showed no signs of tumor growth. There are a few reports, however, of a decline in memory ability after radiation treatment of all types.

Large extrasellar extensions of a pituitary growth must be removed by craniotomy, usually with a transfrontal approach, followed by radiation therapy. Visual field defects often remain, but some improvement in vision can be anticipated.

Pituitary Apoplexy This syndrome, described originally by Brougham and Adams, occurs as a result of infarction of an adenoma that has outgrown its blood supply (see also page 486). It is characterized by the acute onset of headache, opthalmoplegia, bilateral visual loss, and in severe cases, drowsiness or coma, with either subarachnoid hemorrhage or pleocytosis and elevated protein in the CSF. The CT scan or MRI shows infarction of tumor, often with hemorrhage, in and above an enlarged sella. Pituitary apoplexy may threaten life unless the acute addisonian state is treated by dexamethasone (6 to 12 mg q 6 h). Blindness is the other dreaded complication. If there is no improvement after 24 to 48 h or if vision is markedly affected, transnasal decompression of the sella is indicated. Factors that may precipitate the necrosis or hemorrhage of a pituitary tumor are anticagulation, pituitary function testing, radiation, bromocriptine treatment, and head trauma; most cases of necrosis, however, occur spontaneously. Some pituitary adenomas have been cured by this accident.

Ischemic necrosis of the pituitary, followed by hypopituitarism, occurs under a wide variety of clinical circumstances, the most common being in the partum or postpartum period (Sheehan syndrome).

Meningioma of the Sphenoid Ridge This tumor is situated over the lesser wing of the sphenoid bone (Fig. 31-7B). As it grows, it may expand medially to involve structures in the wall of the cavernous sinus, anteriorly into the orbit, or laterally into the temporal bone. Fully 75 percent of such tumors occur in women and the average age at onset is 50 years. Most prominent among the symptoms are a slowly developing unilateral exophthalmos, slight bulging of the bone in the temporal region, and radiologic evidence of thickening or erosion of the lesser wing of the sphenoid bone. Variants of the clinical syndrome include anosmia; oculomotor palsies; painful ophthalmoplegia (sphenoidal fissure and Tolosa-Hunt syndromes, see Table 47-2); blindness and optic atrophy in one eye, sometimes with papilledema of the other eye (Foster Kennedy syndrome); mental changes; seizures (“uncinate fits”); and increased intracranial pressure. Rarely, a skull bruit can be heard over a highly vascular tumor. Sarcomas arising from skull bones, metastatic carcinoma, orbitoethmoidal osteoma, benign giant-cell bone cyst, tumors of the optic nerve, and angiomatas of the orbit must be considered in the differential diagnosis. Scanning by CT and MRI provides the definitive diagnosis. The tumor is resectable without further injury to the optic nerve if the bone has not been invaded.

Meningioma of the Olfactory Groove This tumor originates in arachnoidal cells along the cribiform plate. The diagnosis depends
on the finding of ipsilateral or bilateral anosmia or ipsilateral or bilateral blindness—often with optic atrophy and mental changes. The tumors may reach enormous size before coming to the attention of the physician. If the anosmia is unilateral, it is rarely if ever reported by the patient. The unilateral visual disturbance may consist of a slowly developing central scotoma. Abulia, confusion, forgetfulness, and inappropriate jocularity (Witzelsucht) are the usual psychic disturbances from compression of the inferior frontal lobes (see page 394). The patient may be indifferent to or joke about his blindness. Usually there are radiographic changes along the cribriform plate. The MRI is diagnostic. Except for the largest tumors, surgical removal is possible.

**Meningioma of the Tuberculum Sella**  Cushing was the first to delineate the syndrome caused by this tumor. All of his 23 patients were female. The presenting symptoms were visual failure—a slowly advancing bitemporal hemianopia with a sella of normal size. Often the field defects are asymmetrical, indicating a combined chiasmal-optic nerve involvement. Usually there are no hypothalamic or pituitary deficits. If the tumor is not too large, complete excision is possible. If removal is incomplete or the tumor recurs or undergoes malignant changes, radiation therapy of one type or another is indicated. The outlook is then guarded; several of our patients succumbed within a few years.

**Glioma of the Brainstem**  Astrocytomas of the brainstem are relatively slow-growing tumors that infiltrate tracts and nuclei. They produce a variable clinical picture, depending on their location in the medulla, pons, or midbrain. Most often, this tumor begins in childhood (peak age of onset is 7 years), and 80 percent appear before the 21st year. Symptoms have usually been present for 3 to 5 months before coming to medical notice. In most patients the initial manifestation is a palsy of one or more cranial nerves, usually the sixth and seventh on one side, followed by long tract signs—hemiparesis, unilateral ataxia, ataxia of gait, paraparesis, and hemisensory and gaze disorders. In the remaining patients the symptoms occur in the reverse order—i.e., long tract signs precede the cranial nerve abnormalities. Patients in the latter group survive longer than those whose illness begins with cranial nerve palsies. The combination of a cranial nerve palsy or palsies on one side and motor and/or sensory tract signs on the other always indicates brainstem disease. Headache, vomiting, and papilledema may occur, usually late in the illness, occasionally early. The course is slowly progressive over several years unless some part of the tumor becomes more malignant (anaplastic astrocytoma or glioblastoma multiforme) or, as rarely happens, spreads to the meninges (meningeal gliomatosis), in which instance the illness may terminate fatally within months.

The main problem in diagnosis is to differentiate this disease from a pontine form of multiple sclerosis, a vascular malformation of the pons (usually a cavernous hemangioma), or a brainstem encephalitis, and to distinguish the focal from the diffuse type of glioma (see below). The most helpful procedure in diagnosis and prognosis is MRI (Fig. 31-19).

A careful imaging and clinical study of 87 patients by Barkovich and coworkers has emphasized the importance of distinguishing between diffusely infiltrating and focal nodular tumors. In the more common diffuse type, there is mass effect with hypointense signal on T1-weighted MRI and heterogeneously increased T2 signal, which reflects edema and tumor infiltration. These diffusely infiltrating tumors, usually showing an asymmetrical enlargement of the pons, have a poorer prognosis than the focal or nodular tumors, which tend to occur in the dorsal brainstem and often protrude in an exophytic manner. In a few instances of diffuse brainstem glioma, surgical exploration is necessary to establish the diagnosis (inspection and possibly biopsy). However, the histologic characteristics of a minute biopsy specimen of the tumor are not particularly helpful in determining prognosis or treatment and the general practice is to avoid surgery unless the tumor exhibits unusual clinical behavior or does not conform to the typical MRI appearance of the diffuse type.

**Treatment**  The treatment is radiation, and if increased intracranial pressure develops as a result of hydrocephalus, ventricular shunting of CSF becomes necessary. Adjuvant chemotherapy has not been helpful (Kornblith et al). A series of 16 patients treated by Pollack and colleagues emphasizes the fact that the focal and exophytic brainstem tumors are almost all low-grade astrocytomas; these tumors, in contrast to the more diffuse type, usually respond well to partial resection and permit long-term survival because they recur only slowly and do not undergo malignant transformation. Gangliocytomas or mixed astrogangliocytomas are rare imitators of nodular glioma in the brainstem. The rarer cystic glioma of the brainstem (Fig. 31-19), a pilocytic tumor like its counterpart in the cerebellum, is treated by resection of the mural nodule and, as mentioned earlier, has an excellent prognosis. Landolfi et al emphasized the longer survival in adults with pontine glioma (median 54 months) as compared to children. Most of the patients with pontine tumors with which we are familiar proved to have malignant gliomas.

**Glioma of the Optic Nerves and Chiasm**  This tumor, like the brainstem glioma, occurs most frequently during childhood and adolescence. In 85 percent of cases, it appears before the age of 15 years (average 3.5 years), and it is twice as frequent in girls as in boys (see Cogan). The initial symptoms are diminuion of vision with constricted fields, followed by bilateral field defects of homony-
mous, heteronymous, and sometimes bitemporal type and progressing to blindness and optic atrophy with or without papilledema. Ocular proptosis from the orbital mass is the other main feature. Hypothalamic signs (adiposity, polyuria, somnolence, and genital atrophy) occur occasionally as a result of proximal tumor extension. CT scanning, MRI, and ultrasound will usually reveal the tumor, and radiographs will show an enlargement of the optic foramen (greater than 7.0 mm). This finding and the lack of ballooning of the sella or of suprasellar calcification will exclude pituitary adenoma, craniopharyngioma, Hand-Schuller-Christian disease, and sarcoidosis. In adolescents and young adults, the medial sphenoid, olfactory groove, and intraorbital meningiomas (optic nerve sheath meningioma) are other tumors that cause monocular blindness and proptosis. If the entire tumor is prechiasmatic (the less common configuration), surgical extirpation can be curative. For tumors that have infiltrated the chiasm or are causing regional symptoms and hydrocephalus, partial excision followed by radiation is all that can be offered. Both gliomas and nontumorous gliotic (hamartomatous) lesions of the optic nerves may occur in von Recklinghausen disease; the latter are sometimes impossible to distinguish from optic nerve gliomas.

**Chordoma** This is a soft, jelly-like, gray-pink growth that arises from remnants of the primitive notochord. It is located most often along the clivus (from dorsum sellae to foramen magnum) and in the sacrococcygeal region. It affects males more than females, usually in early or middle adult years, and is one of the rare causes of syndromes involving multiple cranial nerves or the cauda equina. About 40 percent of chordomas occur at each of these two ends of the neuraxis; the rest are found at any point in between. The tumor is made up of cords or masses of large cells with granules of glycogen in their cytoplasm and often with multiple nuclei and intracellular mucoid material. Chordomas are locally invasive, especially of surrounding bone, but they do not metastasize. The cranial neurologic syndrome is remarkable in that all or any combination of cranial nerves from the second to twelfth on one or both sides may be involved. Associated signs in the series of Kendall and Lee were facial pain, conductive deafness, and cerebellar ataxia, the result of pontomedullary and cerebellar compression. A characteristic sign is neck pain radiating to the vertex of the skull on neck flexion. The tumors at the base of the skull may destroy the clivus and bulge into the nasopharynx, causing nasal obstruction and discharge and sometimes dysphagia. Extension to the cerebral epidural space may result in cord compression. Thus, chordoma is one of the lesions that may present both as an intracranial and extracranial mass, the others being meningioma, neurofibroma, glomus jugulare tumor, and carcinoma of the sinuses or pharynx. Plain films of the base of the skull, in addition to MRI, are important in diagnosis. Midline (Wegener) granulomas, histiocytosis, and sarcoidosis also figure in the differential diagnosis. Chondrosarcoma of the clivus produces a similar syndrome.

Treatment of the chordoma is surgical excision and radiation (proton beam or focused gamma radiation). This form of treatment has effected a 5-year cure in approximately 80 percent of patients.

**Nasopharyngeal Growthsthat Erode the Base of the Skull (Nasopharyngeal Transitional Cell Carcinoma, Schmincke Tumor)**

These are rather common in a general hospital; they arise from the mucous membrane of the paranasal sinuses or the nasopharynx near the eustachian tube, i.e., the fossa of Rosenmüller. In addition to symptoms of nasopharyngeal or sinus disease, which may not be prominent, facial pain and numbness (trigeminal), abducens, and other cranial nerve palsies may occur. Diagnosis depends on inspection and biopsy of a nasopharyngeal mass or an involved cervical lymph node and radiologic evidence of erosion of the base of the skull. Bone and CT scans are helpful in diagnosis (Fig. 47-5, page 1188). The treatment is surgical resection (in some cases) and radiation. Carcinoma of the ethmoid or sphenoid sinuses and post-radiation neuropathy, coming on years after the treatment of a nasopharyngeal tumor, may produce similar clinical pictures and are difficult to differentiate. Special imaging techniques, such as the diffusion-weighted MRI sequence, may be useful in separating them. The several syndromes resulting from nasopharyngeal tumors are discussed in Chap. 47, under “Diseases of the Cranial Nerves.”

**Other Tumors of the Base of the Skull** In addition to meningioma, nasopharyngeal tumors, and the other tumors enumerated above, there are a large variety of tumors, rare to be sure, that derive from tissues at the base of the skull and parasinal sinuses, ears, etc., and give rise to distinctive syndromes. Included in this category are osteomas, chondromas, ossifying fibromas, giant-cell tumors of bone, lipomas, epidermoids, teratomas, mixed tumors of the parotid gland, and hemangiomas and cylindromas (adenoid cystic carcinomas of salivary gland origin) of the sinuses and orbit; sarcoid produces the same effect. Most of these tumors are benign, but some have a potential for malignant change. To the group must be added the esthesioneuroblastoma (of the nasal cavity) with anterior fossa extension and, perhaps most common of all of these, the systemic malignant tumors that metastasize to basal skull bones (prostate, lung, and breast being the most common sources) or involve them as part of a multicentric neoplastic process, e.g., primary lymphoma, multiple myeloma, plasmacytoma, and lymphocytic leukemia.

**Suprasellar arachnoid cysts** also occur in this region. CSF flows upward from the interpeduncular cistern but is trapped above the sella by thickened arachnoid (membrane of Liliequist). As the CSF accumulates, it forms a cyst that invaginates the third ventricle; the dome of the cyst may intermittently block the foramina of Monro and cause hydrocephalus (Fox and Al-Mefly). Children with this condition exhibit a curious to-and-fro bobbing and nodding of the head, like a doll with a weighted head resting on a coiled spring. This has been referred to as the “bobble-headed doll syndrome” by Benton and colleagues; it can be cured by emptying the cyst. See-saw and other pendular and jerk types of nystagmus may also result from these suprasellar lesions.

Details of the pathology, embryogenesis, and symptomatology of these rare tumors are far too varied to include in a textbook devoted to principles of neurology.

Table 31-4, and Table 47-1 on page 1180, adapted from Bing’s large neurosurgical service in Berlin, summarizes the known facts about the focal syndromes of the skull base; his authoritative article and the more recent one by Morita and Piepgras, both in the Handbook of Clinical Neurology, are recommended references.

Modern imaging techniques now serve to clarify many of the diagnostic problems posed by these tumors. MRI is particularly helpful in delineating structures at the base of the brain and in the upper cervical region. CT is also capable of determining the absorptive values of the tumor itself and the sites of bone erosion. When the lesion is analyzed in this way, an etiologic diagnosis often becomes possible. For example, the absorptive value of lipomatous tissue is different from that of brain tissue, glioma, blood, and calcium. Bone scans (technetium and gallium) display active

Tumors of the Foramen Magnum

Tumors in the region of the foramen magnum are of particular importance because of the need to differentiate them from diseases such as multiple sclerosis, Chiari malformation, syringomyelia, and bony abnormalities of the craniocervical junction. Failure to recognize these tumors is a serious matter, since the majority are benign and extramedullary, i.e., potentially resectable and curable. If unrecognized, they terminate fatally by causing medullary and high spinal cord compression.

Although these tumors are not numerous (about 1 percent of all intracranial and intraspinal tumors), sizable series have been collected by several investigators (see F. B. Meyer et al for a complete bibliography). In all series, meningiomas, schwannomas, neurofibromas, and dermoid cysts are the most common types; others, all rare, are teratomas, dermoids, granulomas, cavernous hemangiomas, hemangioblastomas, hemangiopericytomas, lipomas, and epidural carcinomas.

Pain in the suboccipital or posterior cervical region, mostly on the side of the tumor, is usually the first and by far the most prominent complaint. In some instances the pain may extend into the shoulder and even the arm. The latter distribution is more frequent with tumors arising in the spinal canal and extending intracranially than the reverse. For uncertain reasons, the pain may radiate down the back, even to the lower spine. Both spine and root pain can be recognized, the latter due to involvement of either the C2 or C3 root or both. Weakness of one shoulder and arm progressing to the ipsilateral leg and then to the opposite leg and arm (“around the clock” paralysis, page 52 is a characteristic but not invariable sequence of events, caused by the encroachment of tumor upon the decussating corticospinal tracts. Occasionally both upper limbs are involved alone; surprisingly, there may be atrophic weakness of the hand or forearm or even intercostal muscles with diminished tendon reflexes well below the level of the tumor, an observation made originally by Oppenheim which we have been able to confirm. Involvement of sensory tracts also occurs; more often it is posterior column sensibility that is impaired on one or both sides, with patterns of progression similar to those of the motor paralysis. Sensation of intense cold in the neck and shoulders has been another unexpected complaint, and also “bands” of hyperesthesia around the neck and back of the head. Segmental brachial sensory loss has been demonstrated in a few of the cases and a Lhermitte sign (really a symptom) of electric-like sensations down the spine and limbs upon flexing the neck has been reported frequently. The cranial nerve signs most frequently conjoined and indicative of intracranial extension are dysphagia, dysphonia, dysarthria, and drooping shoulder (due to vagal, hypoglossal, and spinal accessory involvement); included less often are nystagmus and episodic diplopia, sensory loss over the face and unilateral or bilateral facial weakness, and a Horner syndrome.

The clinical course of such lesions often extends for 2 years or longer, with deceptive and unexplained fluctuations. With dermoid cysts of the upper cervical region, as in the case reported by Adams and Wegner, complete and prolonged remissions from quadripareisis may occur. The important diagnostic procedure is MRI (Fig. 31-20) and, if this is unavailable, CT myelography.

Tumors of the foramen magnum should be differentiated from spinal or brainstem-cerebellar multiple sclerosis, Chiari malformation with syrinx, and chronic adhesive arachnoiditis. Persistent occipital neuralgia with a foramen magnum syndrome is particularly suggestive of a tumor at that site. Treatment is surgical excision (see Hakuba et al) followed by focused radiation if the resection has been incomplete and the tumor is known to be radiosensitive.

REMOTE EFFECTS OF NEOPLASIA ON THE NERVOUS SYSTEM (PARANEOPLASTIC DISORDERS) (Table 31-5)

In the past 50 years there has been delineated a group of neurologic disorders that occur in patients with carcinoma or some other type of neoplasia even though the nervous system is not the site of metastases or direct invasion or compression by the tumor. These so-called paraneoplastic disorders are not specific or confined to cancer, but the two conditions are linked far more frequently than could be accounted for by chance. They assume special importance because the neurologic syndrome in many cases becomes apparent before the underlying tumor is found. Some of the paraneoplastic disorders that involve nerve and muscle—namely, polyneuropathy, polymyositis, and the myasthenic-myopathic syndrome of Lambert-Eaton—are described on pages 1194 and 1259, respectively. Here we present several other paraneoplastic processes that involve the spinal cord, cerebellum, brainstem, and cerebral hemispheres.

Comprehensive accounts of the paraneoplastic disorders may be found in the writings of Posner, Darnell and Posner, and of Dropcho. Some of these disorders are associated with IgG autoantibodies (Table 31-5), but it should be remarked that although certain antibodies are associated with specific syndromes, they are not invariably linked to particular cancers. Furthermore, the
same syndromes and antibodies occur rarely without an evident tumor.

Small-cell cancer of the lung, adenocarcinoma of the breast and ovary, and Hodgkin disease are the tumors most often associated with these disorders, but the paraneoplastic neurologic syndromes occur in only a very small proportion of these cases.

The mechanism(s) by which carcinomas produce their remote effects are poorly understood. Perhaps the most plausible theory, as intimated above, is that they have an autoimmune basis. According to this theory, antigenic molecules are shared by certain tumors and central or peripheral neurons. The immune response is then directed to the shared antigen in both the tumor and the nervous system. The evidence for such an autoimmune mechanism is most clearly exemplified by the Lambert-Eaton syndrome, in which an antibody derived from a tumor binds to voltage-gated calcium channels at neuromuscular junctions (Chap. 53).

Furthermore, in some types of paraneoplastic disorders, there is provocative evidence that the inciting tumor has receptors for the antibody on its surface and the self-binding of the antibody may inhibit tumor growth. This is said to account for the difficulty in detecting diminutive small-cell lung cancers that underlie some of the paraneoplastic syndromes. It should be noted, however, that there is no evidence that suppressing or removing the antibody leads to growth of the tumor.

Paraneoplastic Cerebellar Degeneration

For many years, this disorder was considered to be quite uncommon, but it is perhaps the most characteristic of the paraneoplastic syndromes. In reviewing this subject in 1970, we were able to find only 41 pathologically verified cases; in a subsequent review (Henson and Urich), only a few more cases were added. The actual incidence is much higher than these figures would indicate. At the Cleveland Metropolitan General Hospital, in a series of 1700 consecutive autopsies in adults, there were 5 instances of cerebellar degeneration associated with neoplasm. In the experience of Henson and Urich, about half of all patients with nonfamilial, late-onset cerebellar degeneration proved sooner or later to be harboring a neoplasm. Large series of cases have been reported from the Mayo Clinic and the Memorial Sloan-Kettering Cancer Center (Hammock et al; Anderson et al). We see three or more cases yearly but have also encountered numerous instances of an identical syndrome with no cancer evident and no antibodies (Ropper).

In approximately one-third of the cases, the underlying neoplasm has been in the lung (most often a small-cell carcinoma)—a figure reflecting the high incidence of this tumor. However, the association of ovarian carcinoma and lymphoma, particularly Hodgkin disease, accounting for approximately 25 and 15 percent, respectively, is considerably higher than would be expected on the basis of the frequency of these malignancies. Carcinomas of the breast, bowel, uterus, and other viscera have accounted for most of the remaining cases (Posner).

Characteristically, the cerebellar symptoms have a subacute onset and steady progression over a period of weeks to months; in more than half the cases, the cerebellar signs are recognized before those of the associated neoplasm. Symmetrical ataxia of gait and limbs—affecting arms and legs more or less equally—dysarthria, and nystagmus are the usual manifestations. Striking in fully developed cases has been the severity of the ataxia, matched by few other diseases. Occasionally, myoclonus and opsoclonus or a fast-frequency myoclonic tremor may be associated (“dancing eyes–dancing feet,” as noted below). In addition, there are quite often symptoms and signs not cerebellar in nature, notably diplopia, vertigo, Babinski signs (common in our cases), sensorineural hearing loss, disorders of ocular motility, and alteration of affect and mentality—findings that serve to distinguish paraneoplastic from alcoholic and other varieties of cerebellar degeneration. These are well emphasized in the series of 47 patients collected by Anderson

* In most cases, a particular autoantibody is associated with a specific tumor type rather than with the clinical syndrome (e.g., small-cell lung cancer and polyneuropathy with ANNA 1, breast cancer with anti-Purkinje cell antibody, testicular tumors with anti-Ma). Clinical syndromes similar to each of these may occur with non–small cell lung cancer and lymphoma, most often in the absence of detectable antibodies.
and colleagues and the 55 cases by Peterson et al, who tabulated the additional neurologic features.

The CSF may show a mild pleocytosis (up to 60 cells/mm³ in a few of our patients) and increased protein, or it may be entirely normal. Early in the course of the disease, CT scanning and MRI show no abnormality, but after a few months, atrophy of the brainstem and cerebellum may appear. In a few cases, T2-weighted MRIs disclose an increased signal of the cerebellar white matter (Hammock et al), but this has not been uniform in our experience (Fig. 31-21).

Pathologically, there are diffuse degenerative changes of the cerebellar cortex and deep cerebellar nuclei. Purkinje cells are affected prominently and all parts of the cerebellar cortex are involved. Rarely, there are associated degenerative changes in the spinal cord, involving the posterior columns and spinocerebellar tracts. The cerebellar degeneration is frequently associated with perivascular and meningeal clusters of inflammatory cells. Henson and Urich regard the inflammatory changes as an independent process, part of a subacute paraneoplastic encephalomyelitis (see below). This view is supported by the finding that the specific antibodies that are linked to cerebellar degeneration differ from those that are found in paraneoplastic inflammatory lesions in other parts of the nervous system.

Anti–Purkinje cell antibodies (termed “anti-Yo”) can be found in the sera of about half the patients with paraneoplastic cerebellar degeneration and in the large majority of those related to carcinoma of the breast or female genital tract; the clinical syndrome and this antibody have therefore become closely linked. (Hu, another paraneoplastic antibody, and Yo are taken from the names of patients in whom the antibody was first found.) For example, in the Mayo Clinic series of 32 patients with paraneoplastic cerebellar degeneration, 16 had such antibodies; all were women and most of them had mammary or ovarian cancers. Anderson and colleagues report a similar proportion but point out that several anti-Purkinje antibodies besides the highly characteristic one may be found by special techniques. Death occurred in 4 to 18 months. In an equal number of cases without antibodies, half are men with lung cancer and a few have circulating antibodies of another type (“anti-Hu”) that are more closely linked to the paraneoplastic encephalomyelitis discussed further on. This leaves a proportion who have no circulating antibody but nonetheless are found to have a concealed tumor that must be sought by other ancillary tests. In another small group, it must be conceded that no underlying tumor can be found despite extensive examinations and even at autopsy (Ropper). The death rate in these cases has varied widely from 6 months to several years and depends on the behavior of the underlying tumor.

Whether the anti-Yo antibodies are merely markers of an underlying tumor or the agents of destruction of the Purkinje cells is not known. They have been found to bind to a C-myc protein that initiates a degeneration of Purkinje cells. Regardless of the pathogenic significance of the antibodies, finding them in a patient with the typical neurologic disorder has considerable diagnostic significance. As mentioned above, their presence strongly suggests that there is an underlying breast or ovarian cancer, which may be asymptomatic and small enough to be resected successfully. Other antibodies besides anti-Yo and anti-Hu are found on occasion, such as those against a glutamate receptor in patients with Hodgkin disease (Smit et al). The differential diagnosis is broad as indicated in Table 5-1. The main considerations are a variant of Creutzfeldt-Jakob disease, postinfectious cerebellitis, and various intoxications.

**Treatment**  
Little can be done to modify the cerebellar symptoms, although there are on record several cases in which there was a partial or complete remission of symptoms after removal of the primary tumor (Paone and Jeyasingham). Further, in some cases associated with Hodgkin disease, there has been spontaneous improvement of the cerebellar symptoms. Preliminary reports of aggressive plasma exchange or intravenous immunoglobulin treatment early in the course suggest some benefit, but it should not be assumed that this approach will succeed in most patients, and our own experience in over 10 cases has been discouraging.

**Opsoclonus-Myoclonus-Ataxia Syndrome**

In children, this syndrome is usually a manifestation of neuroblastoma, but it is more common and occurs in adults in relation to breast cancer and small-cell lung cancer. The unique feature of the neuroblastoma form is a response to corticosteroids and ACTH in most children and in some adults, and resolution of the neurologic signs when the neuroblastoma is removed. A subgroup of breast cancer patients produce an antibody that has the neuronal nuclear-binding characteristics of the anti-Hu (antineuronal antibody type 1) antibody discussed below, but it is directed at a different RNA-binding antigen within the cell. It has therefore been termed “anti-Ri” (antineuronal antibody type 2). This antibody is not found in the opsoclonus-ataxic syndrome of neuroblastoma and is present only rarely with small-cell lung cancer. There have also been a limited number of positive serologic tests in children with opsoclonus, apparently without an underlying tumor. A few such patients have had a mild pleocytosis in the CSF; the MRI is usually normal. More complex syndromes have been reported with the anti-Ri antibody, manifest by rigidity and intense stimulus-sensitive myoclonus in addition to the core features of opsoclonus and ataxia.

The neuropathologic findings have not been distinctive; mild
cell loss has been described in the Purkinje cell layer, inferior olives, and brainstem, with mild inflammatory changes (Luque et al.). Besides breast cancer, we have observed the opsoclonus-myoclonus syndrome in a middle-aged woman with bronchial carcinoma and also in a man with gastric carcinoma. Similar cases occur with both cerebellar ataxia and an irregular tremor, which we have interpreted as myoclonic in character. These patients were found to have marked degeneration of the dentate nuclei. The prognosis in this syndrome is somewhat better than that for the other paraneoplastic diseases, but besides a trial of ACTH, there is little that can be done but search for the tumor and resect it if possible.

**Encephalomyelitis Associated with Carcinoma**

The occurrence of regional and bilateral encephalomyelitic changes in association with carcinoma has been described by several authors (Corsellis et al, Henson and Urich, Posner). In most of the reported cases, the encephalitic process has been associated with carcinoma of the bronchus, usually of the small-cell type but all types of neoplasm may be implicated. Histologically, this group of paraneoplastic disorders is characterized by extensive loss of nerve cells, accompanied by microglial proliferation, small patches of necrosis, and marked perivascular cuffing by lymphocytes and monocytes. Foci of lymphocytic infiltration have been observed in the leptomeninges as well. These pathologic changes may involve the brain and spinal cord diffusely, but more often they predominate in a particular part of the nervous system, notably in the medial temporal lobes and adjacent nuclei ("limbic encephalitis," Fig. 31-22), the brainstem (particularly in the medulla), the cerebellum (see above), and the gray matter of the spinal cord. The symptoms will, of course, depend on the location and severity of the inflammatory changes and may overlap. Most cases are subacute, meaning specifically a progression over a few weeks or months, but often the main symptoms in mild form become apparent in a matter of days. Rare instances of remission have been reported.

Anxiety and depression, a confusional-agitated state, hallucinations, retentive memory defect (Korsakoff syndrome), and dementia—singly or in various combinations—are the principal manifestations of so-called *limbic encephalitis* (Gultekin et al). Vertigo, nystagmus, ataxia, nausea and vomiting, and a variety of ocular and gaze palsies reflect the presence of *paraneoplastic brainstem encephalitis*. As indicated above, these symptoms may be joined with cerebellar ataxia, and another group has a sensory neuropathy. We have seen instances of this condition involving only the midbrain and others involving the medulla, the latter with unusual breathing patterns including gasping, inspiratory breathing, and vocal-respiratory incoordination, and yet others with chorea and additional basal ganglionic features. The great variety of clinical presentations can be appreciated from the series by Graus and colleagues of 200 patients: sensory neuropathy, 54 percent; cerebellar ataxia, 10 percent; limbic encephalitis, 9 percent; and others including multiple sites in 11 percent. In most of these cases, MRI shows T2 signal changes in affected regions; in severe cases, zones of focal necrosis may be seen. Odd seizures, including epilepsy partialis continua, have been observed with this disorder, but they must be rare. Sensory symptoms may be related to neuronal loss in the posterior horns, traced to the commonly associated loss of neurons in the dorsal root ganglia (sensory neuronopathy and sensory neuropathy) as mentioned above and discussed further on. All attempts to isolate a virus in these cases have failed.

There may be a slowly progressive, symmetrical or asymmetrical *amyotrophy* of the arms and less often of the legs, traced in two of our patients to poliomyelitic lesions in the anterior horns of the spinal gray matter (see further on). A form characterized mainly by corticospinal degeneration is also reported but has not been found in our clinical material.

Pathologic studies have not entirely clarified these forms of paraneoplastic disorder. In some cases, no changes were demonstrable in the brain, even though there had been a prominent dementia during life. Contrariwise, widespread inflammatory changes may be found without clinical abnormalities having been recorded during life. We believe that these seemingly paradoxical findings may have to do with the thoroughness of the clinical and pathologic examinations.

Most patients with small-cell lung cancer and any of the types of paraneoplastic encephalomyelitis have circulating polyclonal IgG antibodies (*anti-Hu, or antineuronal antibody, type 1*) that bind to the nuclei of neurons in many regions of the brain and spinal cord, dorsal root ganglion cells, and peripheral autonomic neurons. The antibodies are reactive with certain nuclear RNA-binding proteins. Cancers of the prostate and breast and neuroblastoma may rarely produce a similar antibody. The antibody titer is higher in the CSF than in the serum (as it is for anti-Yo with cerebellar degeneration), indicating production of antibody within the nervous system. Low titers of anti-Hu are found in many patients with small-cell cancer who are neurologically normal, probably because these tumors have expressed only low levels of antigens that are recognized by anti-Hu. Recently, antibodies to voltage-gated potassium channels have been identified in patients with limbic encephalitis without cancer (Vincent et al).

Despite a few reports of improvement with plasma exchange or intravenous gamma globulin, the results of treatment have been

---

**Figure 31-22.** Coronal FLAIR MRI from a woman with paraneoplastic “limbic encephalitis” associated with lung cancer and a mild pleocytosis but no detectable autoantibodies. The hippocampi and adjacent regions are involved. Pathologically there proved to be gliosis and a minimal inflammatory infiltrate in these regions.
disappointing. However, those few patients who did improve had treatment from the onset of symptoms, and this is possibly a way of limiting the neuronal loss.

**Paraneoplastic Sensory Neuronopathy**

(See also page 1128)

This, another distinctive paraneoplastic syndrome, is also associated with the anti-Hu antibody. (It should be emphasized, however, that a nondonscript, mainly sensory neuropathy is a more common accompaniment of systemic cancer, and it may or may not be associated with the anti-Hu antibody.) The sensory neuronopathy and neuropathy were first described by Denny-Brown in 1948 and are notable because they served to introduce the modern-day concept of paraneoplastic neurologic disease. The initial symptoms in both processes are numbness or paresthesias, sometimes painful, in a limb or in both feet. There may be lancinating pains at the onset. Over a period of days in some cases, but more typically over weeks, the initially focal symptoms become bilateral and may spread to all limbs and their proximal portions and then to the trunk. It is this widespread and proximal distribution and the involvement of the face, scalp, and often the oral and genital mucosa that marks the process as a sensory ganglionitis and radiculitis and are highly suggestive of a paraneoplastic process. As the illness progresses, all forms of sensation are greatly reduced, resulting in disabling ataxia and pseudoathetoid movements of the outstretched hands. The reflexes are lost, but strength is relatively preserved. Autonomic dysfunction—including constipation or ileus, sicca syndrome, pupillary areflexia, and orthostatic hypotension—is sometimes associated. Also, a virtually pure form of peripheral autonomic failure has been recorded as a paraneoplastic phenomenon (paraneoplastic dysautonomia). One of our patients with sensory neuronopathy had gastric atony with fatal aspiration after vomiting, and another died of unexpected cardiac arrhythmia. Very early in the illness, the electrophysiologic studies may be unexpectedly normal, but this soon gives way to a loss of all sensory potentials, sometimes with indications of a mild motor neuropathy.

The spinal fluid often contains an elevated protein and a few lymphocytes. As with paraneoplastic encephalomyelitis, most of the cases associated with small-cell lung cancer demonstrate the anti-Hu antibody. As mentioned, neuropathy and encephalomyelitis often occur together. The sensory neuronopathy-ganglionopathy that is related to Sjögren disease and an idiopathic variety often occur together. The sensory neuronopathy-ganglionopathy that is related to Sjögren disease and an idiopathic variety cannot be certain that the condition was not a chance occurrence of most of the idiopathic variety of motor neuron disease. Nevertheless, this is such a rare cause of motor neuron disease that an evaluation for carcinoma is uncertain.

Henson and Urich have drawn attention to another rare spinal cord disorder usually associated with carcinoma of the lung. This takes the form of large, wedge-shaped necrotic lesions scattered throughout the cord, affecting mainly the white matter of the posterior and lateral columns. The clinical correlates of this disorder are also unclear.

A *subacute motor neuronopathy* is yet another spinal cord disorder that occurs as a remote effect of bronchogenic carcinoma, Hodgkin disease, and other lymphomas, as mentioned earlier in the discussion of encephalomyelitis (see Schold et al). Some cases take the form of a relatively benign, purely motor weakness of the limbs, the disease and severity of which are independent of the underlying neoplasm. Other cases are severe and progressive, causing respiratory failure and death, thus simulating amyotrophic lateral sclerosis (ALS); some of these will have the anti-Hu antibody (Verma et al, Forsyth et al). The basic neuropathologic change is a depletion of anterior horn cells; also seen are inflammatory changes and neuronophagia, as in chronic poliomyelitis. In addition, the few autopsied cases have shown gliosis of the posterior columns, pointing to an asymptomatic affection of the primary sensory neuron, as well as a reduction in the number of Purkinje cells.

Forsyth and colleagues have subdivided their cases of *paraneoplastic motor neuron syndromes* into three groups: (1) rapidly progressive amyotrophy and fasciculations with or without brisk reflexes—all of their three patients displayed anti-Hu antibodies, two with small-cell lung cancer and one with prostate cancer; (2) a predominantly corticospinal syndrome that affected the oropharyngeal or limb musculature, without definite evidence of denervation, thus resembling primary lateral sclerosis—all were breast cancer patients but none showed antineuronal antibodies; and (3) a syndrome indistinguishable from ALS in six patients with breast or small-cell lung cancer, Hodgkin disease, or ovarian cancer, none of whom had antineuronal antibodies. In the last two groups one cannot be certain that the condition was not a chance occurrence of the idiopathic variety of motor neuron disease. Nevertheless, this is such a rare cause of motor neuron disease that an evaluation for tumor is not required in the typical case of ALS.

**Other Paraneoplastic Disorders**

Several more recently discovered antibodies, such as CRMP-5 and anti-Ma1 and -Ma2, have been detected in cases of brainstem encephalomyelitis; the latter cross-react with testicular antigens (Dalmay et al; Voltz et al). While rare, the clinical syndromes associated with the anti-Ma antibody and testicular tumors have been diverse: limbic, brainstem, or hypothalamic inflammation and an ataxicopsoclonic syndrome that is more typical of anti-Ri antibody (see above). The more recently discovered antibody CRMP-5 (collapsin-responsive mediator protein) is reported to be second in frequency to anti-Hu. Lung carcinoma has been the most common source in the series of Yu and colleagues, with thymoma, renal cell, and other
neoplasms accounting for a few of the cases. The clinical features have been as diverse as for anti-Hu, including seizures, dementia, confusion, depression, as well as a variety of peripheral and cranial neuropathies and, surprisingly, the Lambert-Eaton syndrome.

**Optic Neuropathy**  An optic neuropathy is the most specific associated syndrome with the CRMP antibody, as described by Cross and colleagues. There is subacute visual loss, disc swelling, and a cellular reaction in the vitreous. Most patients have features of another paraneoplastic syndrome. Others have remarked on the occurrence of chorea as a presenting symptom and basal ganglionic changes in MRI. It is difficult for us to make sense of the clinical features aside from the optic neuropathy (really an optic neuritis), but they suggest a type of periventricular inflammatory encephalitis and neuritis comparable to the anti-Hu syndromes. Presumably this antibody accounts for some of the odd subacutely progressive syndromes previously thought to be antibody-negative; testing for this antibody might be included when an odd paraneoplastic syndrome is suspected. The heterogeneity of antibody response to these expressed proteins may account for different clinical manifestations of the immune process, but there is no certain evidence yet of their pathogenetic role.

**Stiff-Man Syndrome**  Occasionally this disorder (page 1279) occurs as a paraneoplastic syndrome. Lesser degrees of unexplained mild rigidity are seen from time to time, due perhaps to loss of spinal cord interneurons. In what might be called “stiff-woman syndrome,” Folli and associates have described three patients with breast cancer who developed a state of generalized motor hyperexcitability and rigidity. These patients generally have no antibodies to glutamic acid decarboxylase, as in the sporadic cases of “stiff-man syndrome”; probably there are antibodies to other synaptic proteins.

**Retinopathy**  In recent years, there have been several reports of retinopathy as a paraneoplastic syndrome that is distinct from the above-described optic neuropathy. Small-cell carcinoma of the lung has been the most common underlying malignancy. In about half of the reported cases, retinal symptoms preceded the discovery of the tumor by several months. The lesion is in the photoreceptor cells, and antiretinal antibodies (directed against a calcium-binding protein, recoverin) have been identified in the serum. Photosensitivity, ring scotomas, and attenuation of the retinal arterioles are the main clinical features; Jacobson and coworkers have suggested that they constitute a diagnostic triad.

*The Lambert-Eaton syndrome* is the most common paraneoplastic syndrome; it is associated with antibodies directed against calcium channels, as mentioned earlier. This disorder is discussed on page 1259. Basal ganglia syndromes, chorea in particular, are associated with the anti-Hu and CRMP-5 antibodies as already noted. A myoclonus syndrome without ataxia or opsoclonus is reported from time to time in the literature and probably is a derivative of one of the better characterized antibody diseases.

Another peculiar syndrome associated with prostate cancer, which we have encountered only once, was described by Baloh and colleagues prior to the discovery of most of the currently known paraneoplastic antibodies. These patients display brainstem signs, particularly loss of horizontal gaze, and facial and pharyngeal spasms or abdominal myoclonus. Whether this process will be subsumed under one or another of the known antibody syndromes is not known, but it is notable because prostate cancer otherwise rarely gives rise to paraneoplastic disease.

Isolated case reports relating neuromyelitis optica and optic neuritis to neoplasm cannot presently be evaluated.

**Radiation Injury of the Brain**

Injury to the CNS from radiation is appropriately discussed here, since it occurs mainly in relation to therapy of brain tumors. Three syndromes of radiation damage have been delineated: acute, early delayed, and late delayed, although these stages often blend into one another. The acute reaction may begin during the latter part of a series of fractionated treatments or soon thereafter. There may be a seizure, a transitory worsening of the tumor symptoms, or signs of increased intracranial pressure. The EEG reveals delta waves but with preserved background activity. Although the condition has been attributed to brain edema, this is not visible in MRI scans and its basis is unknown. The symptoms subside in days to weeks. Corticosteroids are usually administered, but with the exception of cases with demonstrable edema, their effect is uncertain.

The early delayed syndrome has been more troublesome in our experience. As with the acute syndrome, focal tumor symptoms may increase, and as seen on MRI (Fig. 31-23), the tumor mass enlarges, raising the possibility of further tumor growth, but again the symptoms usually resolve within 6 to 8 weeks. Postmortem examination discloses extensive demyelination, loss of oligodendrocytes beyond the confines of the tumor, and varying degrees of tissue necrosis. Possibly the administration of dexamethasone or a similar corticosteroid hastens resolution.

The late delayed injury is the most serious of the three complications. Here one finds—in structures adjacent to a cerebral neoplasm, the pituitary gland, or other structures of the head and neck—a coagulation necrosis of the white matter of the brain and occasionally of the brainstem. In some areas, the tissue undergoes

![Figure 31-23. MRI showing early delayed radiation change in white matter of both frontal lobes, particularly severe on the right in the region of the treated glioma.](image-url)
softening and liquefaction, with cavitation. With lesser degrees of injury, the process is predominantly a demyelinating one, with partial preservation of axons. Later reactions are thought to be due to diffuse vascular changes as a result of radiation energy. Endothelial cells frequently multiply and, since ionization injures dividing cells, the vessels are most vulnerable. The result is hyaline thickening of vessels with fibrinoid necrosis and widespread microthrombosis. There is a lesser degree of damage to glial cells. Neurons are relatively resistant.

The symptoms of delayed injury, coming on 3 months to many years after radiation therapy, are either those of a subacutely evolving mass, difficult to separate from those of tumor growth, or of a subacute dementia. The clinical pattern varies with the site of the lesion: focal or generalized seizures, impairment of mental function, and sometimes increased intracranial pressure. Whole-brain radiation for metastatic tumor or acute lymphoblastic leukemia can lead to multifocal zones of necrosis and holohemispheric spongiform changes in the white matter, with diffuse cerebral atrophy and enlarged ventricles. Progressive dementia, ataxia, and urinary incontinence are the main clinical features of this state (DeAngelis et al). In its mildest form there are no radiographic changes aside from the tumor, but the patient becomes mentally dull, slightly disoriented, and often sleepy for large parts of the day. Panhypopituitarism is another complication of whole-brain radiotherapy, particularly in children, who may also suffer growth retardation. Radiation necrosis of the spinal cord is described on page 1055.

In the production of radiation necrosis, the total and fractional doses of radiation and the time over which treatment is administered are obviously important factors, but the exact amounts that produce such damage cannot be stated. Accepted levels of large-field radiation are tolerated in amounts approaching 6000 cGy, provided it is given in small daily doses (200 to 300 cGy) 5 days per week over a period of 6 weeks [1cGY = 100 rads (radiation absorbed dose), or 100 ergs per gram of irradiated material]. Other factors, still undefined, must play a part, since similar courses of radiation treatment may damage one patient and leave another unaffected. The severe necrotizing encephalopathy that has followed the combined use of methotrexate (intrathecally but also intravenously) was discussed earlier, under "Involvement of the Nervous System in Leukemia," the condition in which it was first described and formerly was most prevalent.

CT scans show a low-density contrast-enhancing lesion, and by angiography there is an avascular mass. MRI is somewhat more sensitive in distinguishing radiation necrosis from tumor and peri-tumor products, but positron emission tomography (PET) is the most reliable way of making this distinction, perhaps obviating the need for biopsy (Glantz et al). Single-photon emission tomography (SPECT) can be equally useful for this purpose (Carvalho et al). Treatment has consisted of corticosteroids, which may cause regression of symptoms and of edema surrounding the lesion. Very high doses may be necessary, 40 mg or more of dexamethasone (or its equivalent). Rarely, surgical resection has been attempted, with indifferent results.

It is also known that tumors, usually sarcomas, can be induced by radiation, as mentioned earlier (Cavin et al). While well documented, this occurs rarely and only after an interval of many years. We have also seen two cases of fibrosarcoma of the brachial plexus region in the radiation field for breast tumors (Gorson et al). These lesions appeared more than 10 years after the initial treatment, and many cases of even longer latency are on record.

Tumors of the spinal cord and peripheral nerves are discussed in Chaps. 44 and 46, respectively. The various neurologic effects of chemotheraphy for systemic tumors, especially polynuropathy, are discussed in Chaps. 43 and 46.

CHAPTER 32

INFECTIONS OF THE NERVOUS SYSTEM
(BACTERIAL, FUNGAL, SPIROCHETAL, PARASITIC)
AND SARCOIDOSIS

This chapter is concerned mainly with the pyogenic or bacterial infections of the central nervous system (CNS), i.e., bacterial meningitis, septic thrombophlebitis, brain abscess, epidural abscess, and subdural empyema. The granulomatous infections of the CNS—namely tuberculosis, syphilis and other spirochetal infections, and certain fungal infections—are also discussed in some detail. In addition, consideration is given to sarcoid, a granulomatous disease of uncertain etiology, and to the CNS infections and infestations caused by certain rickettsias, protozoa, worms, and ticks.

A number of other infectious diseases of the nervous system are more appropriately discussed elsewhere in this book. Diseases due to bacterial exotoxins—diphtheria, tetanus, botulism—are considered with other toxins that affect the nervous system (Chap. 43). Leprosy, which is essentially a disease of the peripheral nerves, is described in Chap. 46, and trichinosis, mainly a disease of muscle, in Chap. 48. Viral infections of the nervous system, because of their frequency and importance, are allotted a chapter of their own (Chap. 33).

PYOGENIC INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Pyogenic infections reach the intracranial structures by one of two pathways, either by hematogenous spread (emboli of bacteria or infected thrombi) or by extension from cranial structures (ears, paranasal sinuses, osteomyelitic foci in the skull, penetrating cranial injuries, or congenital sinus tracts). In a number of cases, infection is iatrogenic, being introduced in the course of cerebral or spinal surgery, the placement of a ventriculoperitoneal shunt, or due to arterial occlusion (thrombosis or embolism) or venous occlusion (thrombophlebitis) appears to be a common and perhaps necessary antecedent.

The mechanism of meningitis and brain abscess from infection of the middle ear and paranasal sinuses is easier to understand. The cranial epidural and subdural spaces are practically never the sites of blood-borne infections, in contrast to the spinal epidural space, where such infections are almost always introduced by the hematogenous route. Furthermore, the cranial bones and the dura mater (which essentially constitutes the inner periosteum of the skull) protect the cranial cavity against the ingress of bacteria. This protective mechanism may fail if suppuration occurs in the middle ear, mastoid cells, or frontal, ethmoid, and sphenoid sinuses. Two pathways from these sources have been demonstrated: (1) infected thrombi may form in diploic veins and spread along these vessels into the dural sinuses (into which the diploic veins flow), and from there, in retrograde fashion, along the meningeal veins into the brain, and (2) an osteomyelitic focus may form, with erosion of the inner table of bone and invasion of the dura, subdural space, pia-arachnoid, and even brain. Each of these pathways has been observed by the authors in some fatal cases of epidural abscess, subdural empyema, meningitis, cranial venous sinusitis and meningeal thrombophlebitis, and brain abscess. However, in many cases coming to autopsy, the pathway of infection cannot be determined.

With a hematogenous infection in the course of a bacteremia, usually a single type of virulent organism gains entry to the cranial cavity. In the adult the most common pathogenic organisms are pneumococcus (Streptococcus pneumoniae), meningococcus (Neisseria meningitides), Haemophilus influenzae, Listeria monocytogenes, and staphylococcus; in the neonate, Escherichia coli and group B streptococcus; in the infant and child, H. influenzae. By contrast, when septic material embolizes from infected lungs, pulmonary arteriovenous fistulas, or congenital heart lesions or extends directly from ears or sinuses, more than one type of bacterial flora common to these sources may be transmitted. Such “mixed infections” pose difficult problems in therapy. Occasionally in these latter conditions, the demonstration of the causative organisms may be unsuccessful, even from the pus of an abscess (mainly because of inadequate culturing techniques for anaerobic organisms and the prior use of antibiotics). Infections that follow neurosurgery or the insertion of a cranial appliance are usually staphylococcal; a small number are due to mixed flora, including anaerobic ones, or the enteric organisms. In determining the most likely invading organism, the age of the patient, the clinical setting of the infection (community-acquired, postsurgical, or nosocomial), the immune status of the patient, and evidence of systemic and local cranial disease all must be taken into account.
ACUTE BACTERIAL MENINGITIS  
(LEPTOMENINGITIS)

The Biology of Bacterial Meningitis

The immediate effect of bacteria or other micro-organisms in the subarachnoid space is to cause an inflammatory reaction in the pia and arachnoid as well as in the cerebrospinal fluid (CSF). Since the subarachnoid space is continuous around the brain, spinal cord, and optic nerves, an infective agent gaining entry to any one part of the space may spread rapidly to all of it, even its most remote recesses; in other words, meningitis is always cerebrospinal. Infection also reaches the ventricles, either directly from the choroid plexuses or by reflux through the foramina of Magendie and Luschka.

The first reaction to bacteria or their toxins is hyperemia of the meningeal venules and capillaries and an increased permeability of these vessels, followed shortly by exudation of protein and the migration of neutrophils into the pia and subarachnoid space. The subarachnoid exudate increases rapidly, particularly over the base of the brain; it extends into the sheaths of cranial and spinal nerves and, for a very short distance, into the perivascular spaces of the cortex. During the first few days, mature and immature neutrophils, many of them containing phagocytosed bacteria, are the predominant cells. Within a few days, lymphocytes and histiocytes increase gradually in relative and absolute numbers. During this time there is exudation of fibrinogen, which is converted to fibrin after a few days. In the latter part of the second week, plasma cells appear and subsequently increase in number. At about the same time the cellular exudate becomes organized into two layers—an outer one, just beneath the arachnoid membrane, made up of neutrophils and fibrin, and an inner one, next to the pia, composed largely of lymphocytes, plasma cells, and mononuclear cells or macrophages. Although fibroblasts begin to proliferate early, they are not conspicuous until later, when they take part in the organization of the exudate, resulting in fibrosis of the arachnoid and occlusion of pockets of exudate.

During the process of resolution, the inflammatory cells disappear in almost the same order as they had appeared. Neutrophils begin to disintegrate by the fourth to fifth day, and soon thereafter, with treatment, no new ones appear. Lymphocytes, plasma cells, and macrophages disappear more slowly, and a few lymphocytes and mononuclear cells may remain in small numbers for several months. The completeness of resolution depends to a large extent on the stage at which the infection is arrested. If it is controlled in the very early stages, there may not be any residual change in the brain substance, or it may develop subdural effusion. This happens far more often in infants than in adults; according to Snedeker and coworkers, approximately 40 percent of infants with meningitis who are less than 18 months of age develop subdural effusions. As a rule, there is no subdural pus, only a sterile yellowish exudate. In an even higher percentage of cases, small amounts of fibrinous exudate are found in microscopic sections that include the spinal dura.

When fibrinopurulent exudate accumulates in large quantities around the spinal cord, it blocks off the spinal subarachnoid space. Hydrocephalus is produced by exudate in the foramina of Magendie and Luschka or in the subarachnoid space around the pons and midbrain, interfering with the flow of CSF from the lateral recesses of the fourth ventricle and cisterna magna to the basal cisterns and cerebral convexities. In the later stages, fibrous subarachnoid adhesions are an additional and sometimes the most important factor interfering with the circulation of CSF. An infrequent late sequela of bacterial meningitis is therefore chronic adhesive arachnoiditis or chronic meningomyelitis.

In the early stages of meningitis, very little change in the substance of the brain can be detected. Neutrophils appear in the Virchow-Robin perivascular spaces but enter the brain only if there is necrosis. After several days, microglia and astrocytes increase in number, at first in the outer zone and later in all layers of the cortex. The associated nerve cell changes may be very slight. Obviously some disorder of the cortical neurons must take place from the beginning of the infection to account for the stupor, coma, and convulsions that are so often observed, but several days must elapse before any change can be demonstrated microscopically. It is uncertain whether these cortical changes are due to the diffusion of toxins from the meninges, to a circulatory disturbance, or to some other factor, such as increased intracranial pressure. Restated, the aforementioned changes are not due to invasion of brain substance...
by bacteria and should therefore be regarded as a noninfectious encephalopathy. When macrophages and astrocytes are exposed to endotoxins in vitro, the cells synthesize and release cytokines, among which are interleukin-1 and tumor necrosis factor. These cytokines are believed to stimulate and modulate the local immune response but may also affect cortical neurons.

In the early stages of meningitis, there is little change in the ependyma and the subependymal tissues; but in later stages, conspicuous changes are invariably found. The most prominent finding is infiltration of the subependymal perivascular spaces and often of the adjacent brain tissue with neutrophilic leukocytes and later with lymphocytes and plasma cells. Microglia and astrocytes proliferate, the latter sometimes overgrowing and burying remnants of the ependymal lining. We believe that the bacteria pass through the ependymal lining and set up this inflammatory reaction in part because this sequence of events is favored by a developing hydrocephalus, which stretches and breaks the ependymal lining. Collections of subependymal astrocytes then begin to protrude into the ventricle, giving rise to a granular ependymitis, which, if prominent, may narrow and obstruct the aqueduct of Sylvius. The choroid plexus is at first congested, but within a few days it becomes infiltrated with neutrophils and lymphocytes and eventually may be covered with exudate. As in the case of the meningeal exudate, lymphocytes, plasma cells, and macrophages later predominate. Eventually there is organization of the exudate covering the plexus.

As any meningitis becomes more chronic, the pia-arachnoid exudate tends to accumulate around the base of the brain (basilar meningitis), obstructing the flow of CSF and giving rise to hydrocephalus. The exudate may also encircle cranial nerves and lead to focal cranial neuropathies.

The reader may question this long digression into matters that are more pathologic than clinical, but only a knowledge of the morphologic features of meningitis enables one to understand the clinical state and its sequelae. The meningeal and ependymal reactions to bacterial infection and the clinical correlates of these reactions are summarized in Table 32-1, which may be consulted together with this section.

Types of Bacterial Meningitis

Almost any bacterium gaining entrance to the body may produce meningitis, but by far the most common are _H. influenzae_, _N. meningitidis_, and _Strep. pneumoniae_, which account for about 75 percent of sporadic cases. Infection with _L. monocytogenes_ is now the fourth most common type of nonsurgical bacterial meningitis in adults. The following are less frequent causes: _Staph. aureus_ and group A and group D streptococci, usually in association with brain abscess, epidural abscess, head trauma, neurosurgical procedures, or cranial thrombophlebitis; _E. coli_ and group B streptococci in newborns; and the other Enterobacteriaeae, such as Klebsiella, Proteus, and _Pseudomonas_, which are usually a consequence of lumbar puncture, spinal anesthesia, or shunting procedures to relieve hydrocephalus. Rarer meningeal pathogens include _Salmonella_, _Shigella_, _Clostridium_, _Neisseria gonorrhoeae_, and _Acinetobacter calcoaceticus_, which may be difficult to distinguish from _Haemophilus_ and _Neisseria_. In endemic areas, _mycobacterial infections_ (to be considered further on) are as frequent as those due to other bacterial organisms. They now assume greater importance in developed countries as the number of immunosuppressed persons increases.

Epidemiology

Pneumococcal, influenzal (_H. influenzae_), and meningococcal forms of meningitis have a worldwide distribution, occurring mainly during the winter and early spring and, in the case of the first two, also in the fall, and predominating slightly in males. Each has a relatively constant incidence, although epidemics of meningococcal meningitis seem to occur roughly in 10-year cycles. Drug-resistant strains appear with varying frequency, and such information, gleaned from surveillance reports issued by the Centers for Disease Control and Prevention and from reports of local health agencies and hospital infection surveillance, are of great practical importance.

_H. influenzae_ meningitis, formerly encountered mainly in infants and young children, has been nearly eliminated in this age group as a result of vaccination programs in developed countries. It continues to be common in less developed nations and is now occurring with increasing frequency in adults (in the United States there are 15,000 cases each year). _Meningococcal meningitis_ occurs most often in children and adolescents but is also encountered throughout much of adult life, with a sharp decline in incidence after the age of 50. _Pneumococcal meningitis_ predominates in the very young and in older adults. Perhaps the greatest change in the epidemiology of bacterial meningitis, aside from the one related to _H. influenzae_ vaccination, has been the increasing incidence of nosocomial infections, accounting for 40 percent of cases in large urban hospitals (Durand and colleagues); staphylococcus and gram-negative bacilli account for a large proportion of these. Noteworthy is the report of Schuchat et al, who found that in 1995, some 5 years after the introduction of the conjugate _H. influenzae_ vaccine, the overall incidence of bacterial meningitis in the United States had been halved. The yearly incidence rate (per 100,000) of the responsible pathogens is now approximately as follows: _Strep. pneumoniae_, 1.1; _N. meningitidis_, 0.6; group B streptococcus (newborns), 0.3; _L. monocytogenes_, 0.2; and _H. influenzae_, 0.2.

Pathogenesis

The three most common meningeal pathogens are all normal inhabitants of the nasopharynx in a significant part of the population and depend on antiphagocytic capsular or surface antigens for survival in the tissues of the infected host. To a large extent they express their pathogenicity by extracellular proliferation. It is evident from the frequency with which the carrier state is detected that nasal colonization is not a sufficient explanation of infection of the meninges. Factors that predispose the colonized patient to invasion of the bloodstream, which is the usual route by which these bacteria reach the meninges, are obscure but include antecedent viral infections of the upper respiratory passages or, in the case of _Strep. pneumoniae_, infections of the lung. Once blood-borne, it is evident that pneumococci, _H. influenzae_, and meningococci possess a unique predilection for the meninges, although the precise factors that determine this meningeal localization are not known. Whether the organisms enter the CSF via the choroid plexus or meningeal vessels is also unknown. It has been variously postulated that the entry of bacteria into the subarachnoid space is facilitated by disruption of the blood-CSF barrier by trauma, circulating endotoxins, or an initial viral infection of the meninges. These organisms, being commensal in most persons, create immunity, but bacteria may nonetheless penetrate the mucosa. Certain features of the organisms...
enhance their ability to cause infection; this is particularly true of the meningococcus (see Rosenstein et al).

Avenues other than the bloodstream by which bacteria can gain access to the meninges include congenital neuroectodermal defects; craniotomy sites; diseases of the middle ear and paranasal sinuses, particularly perilymphatic fistulas; skull fractures; and, in cases of recurrent infection, dural tears from remote minor or major trauma. Occasionally a brain abscess may rupture into the subarachnoid space or ventricles, thus infecting the meninges. The isolation of anaerobic streptococci, *Bacteroides, Actinomyces*, or a mixture of micro-organisms from the CSF should suggest the possibility of a brain abscess with an associated meningitis.

### Clinical Features

**Adults and Children**  The early clinical effects of acute bacterial meningitis are fever, severe headache, and stiffness of the neck (resistance to passive movement on forward bending), sometimes with generalized convulsions and a disorder of consciousness (i.e., drowsiness, confusion, stupor, and coma). Flexion at the hip and knee in response to forward flexion of the neck (Brudzinski sign) and inability to completely extend the legs (Kernig sign) have the same significance as stiff neck but are less consistently elicitable. Basically, all of these signs are part of a flexor protective reflex (one of the “nocifensive” responses in Fulton’s terms). Stiffness of the neck that is part of paratonic or extrapyramidal rigidity should not be mistaken for that of meningitis. The former is more or less equal in all directions of movement, in distinction to that of meningitis, which is present only or predominantly on forward flexion. Whether it is stiffness in the initial few degrees of flexion of the neck or in the subsequent part of the movement that is more specific for meningitis has been debated; our experience has been that the latter is more sensitive but also proves to be mistaken for other disorders; therefore the first may be more specific for meningitis. Diagnosis of meningitis may be difficult when the initial manifestations consist only of fever and headache, when stiffness

### Table 32-1

**Pathologic-clinical correlations in acute, subacute, and chronic meningeal reactions**

<table>
<thead>
<tr>
<th>I. In acute meningeal inflammation:</th>
</tr>
</thead>
<tbody>
<tr>
<td>A. <strong>Pure pia-arachnoiditis</strong>: headache, stiff neck, Kernig and Brudzinski signs. These signs depend on the activation of protective reflexes that shorten the spine and immobilize it. Extension of the neck and flexion of the hips and knees reduce stretch on inflamed spinal structures; resistance to forward flexion of the neck (Brudzinski sign) and extension of the legs (Kernig sign) involves maneuvers that oppose these protective flexor reflexes.</td>
</tr>
<tr>
<td>B. <strong>Subpial encephalopathy</strong>: confusion, stupor, coma, and convulsions are related to this lesion. The tissue beneath the pia is not penetrated by bacteria; hence the change is probably toxic (e.g., cytokines). Cerebral infarction due to cortical vein thrombosis may underlie these symptoms in some cases.</td>
</tr>
<tr>
<td>C. <strong>Inflammatory or vascular involvement of cranial nerve roots</strong>: ocular palsies, facial weakness, and deafness are the main clinical signs. Note: Deafness may also be due to middle ear infection, to extension of meningeal infection to the inner ear, or to toxic effects of antimicrobial agents.</td>
</tr>
<tr>
<td>D. <strong>Thrombosis of meningeal veins</strong>: focal seizures, focal cerebral defects such as hemiparesis, aphasia (rarely prominent), may appear on the third or fourth day after the onset of meningeal infection, but more often after the first week. There may be spinal cord infarction.</td>
</tr>
<tr>
<td>E. <strong>Ependymitis, choroidal plexitis</strong>: it is doubtful if there are any recognizable clinical effects aside from those of the associated menigitis and hydrocephalus.</td>
</tr>
<tr>
<td>F. <strong>Cerebellar or cerebral hemisphere herniation</strong>: due to swelling (as in B), causing upper cervical cord compression with quadriplegia or signs of midbrain–third nerve compression.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>II. In more subacute and chronic forms of meningitis:</th>
</tr>
</thead>
<tbody>
<tr>
<td>A. <strong>Tension hydrocephalus</strong>, due at first to purulent exudate around the base of the brain, later to meningeal fibrosis, and rarely to aqueductal stenosis. In adults, there are variable degrees of impairment of consciousness, decorticative postures (arms flexed, legs extended), grasp and suck reflexes, and sphincteric incontinence. CSF pressure may at first be elevated; as the ventricles enlarge and the choroid plexuses are compressed, it may fall to within limits of normal (normal-pressure hydrocephalus). In infants and young children, the main signs are enlarging head, frontal bossing, inability to look upward (eyes turn down and lids retract on effort to look up—“sunset” sign); in mildest form, there are only psychomotor retardation, unsteadiness of gait, and incontinence.</td>
</tr>
<tr>
<td>B. <strong>Subdural effusion</strong>: impaired alertness, refusal to eat, vomiting, immobility, bulging fontanels, and persistence of fever despite clearing of CSF. In infants, the effusion causes an exaggerated transillumination. If fever is present but CSF pressure is normal, and if one-sided cerebral signs are clearly in evidence, thrombophlebitis with infarction of underlying brain is the leading possibility.</td>
</tr>
<tr>
<td>C. <strong>Extensive venous or arterial infarction</strong>: unilateral or bilateral hemiplegia, decorticate or decerebrate rigidity, cortical blindness, stupor or coma with or without seizures.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>III. Late effects or sequelae:</th>
</tr>
</thead>
<tbody>
<tr>
<td>A. <strong>Meningeal fibrosis around optic nerves or around spinal cord and roots</strong>: blindness and optic atrophy, spastic paraparesis with sensory loss in the lower segments of the body (opticochiasmatic arachnoiditis and meningomyelitis, respectively).</td>
</tr>
<tr>
<td>B. <strong>Chronic meningoencephalitis with hydrocephalus</strong>: dementia, stupor or coma, and paralysis (e.g., general paralysis of the insane).</td>
</tr>
<tr>
<td>If lumbo-sacral posterior roots are chronically damaged, a tabetic syndrome results.</td>
</tr>
<tr>
<td>C. <strong>Persistent hydrocephalus in the child</strong>: blindness, arrest of all mental activity, bilateral spastic hemiplegia.</td>
</tr>

</table>
of the neck has not yet developed, or when there is only pain in the neck or abdomen or a febrile confusional state or delirium. Also, stiffness of the neck may not be apparent in the deeply stuporous or comatose patient or in the infant or the elderly, as indicated further on.

The symptoms comprised by the meningitic syndrome are common to the three main types of bacterial meningitis, but certain clinical features and the setting in which each of them occurs correlate more closely with one type than another.

**Meningococcal meningitis** should be suspected when the evolution is extremely rapid (delirium and stupor may supervene in a matter of hours), when the onset is attended by a petechial or purpuric rash or by large ecchymoses and lividity of the skin of the lower parts of the body, when there is circulatory shock, and especially during local outbreaks of meningitis. Since a petechial rash accompanies approximately 50 percent of meningococcal infections, its presence dictates immediate institution of antibiotic therapy, even though a similar rash may be observed with certain viral infections. Persistent fever of any cause. Persistent focal cerebral lesions or intractable headache, stiff neck may be absent, and one has only the nonspecific signs of a systemic illness—fever, irritability, drowsiness, vomiting, convulsions—and a bulging fontanel to suggest the presence of meningeal infection. Signs of meningeal irritation do occur, but only late in the course of the illness. A high index of suspicion and liberal use of the lumbar puncture needle are the keys to early diagnosis. Lumbar puncture is ideally performed before any antibiotics are administered for other neonatal infections. An antibiotic regimen sufficient to control a septicemia may allow a meningeal infection to smolder and to flare up after antibiotic therapy for the systemic infection has been discontinued.

A number of other facts about the natural history of neonatal meningitis are noteworthy. It is more common in males than in females, in a ratio of about 3:1. Obstetric abnormalities in the third trimester (premature birth, prolonged labor, premature rupture of fetal membranes) occur frequently in mothers of infants who develop meningitis in the first weeks of life. The most significant factor in the pathogenesis of the meningitis is maternal infection (usually a urinary tract infection or puerperal fever of unknown cause). The infection in both mother and infant is most often due to gram-negative enterobacteria, particularly *E. coli*, and group B streptococci and less often to *Pseudomonas*, *Listeria*, *Staph. aureus* or *epidermidis* (formerly *albus*), and group A streptococci. Analysis of postmortem material indicates that in most cases infection occurs at or near the time of birth, although clinical signs of meningitis may not become evident until several days or a week later.

In infants with meningitis, one should be prepared to find a unilateral or bilateral sympathetic subdural effusion regardless of bacterial type. Young age, rapid evolution of the illness, low polymorphonuclear cell count, and markedly elevated protein in the CSF correlate to some extent with the formation of effusions, according to Snedeker and coworkers. Also, these attributes greatly increase the likelihood of the meningitis being associated with neurologic signs. Transillumination of the skull is the simplest method of demonstrating the presence of an effusion, but computed tomography (CT) and magnetic resonance imaging (MRI) are the definitive diagnostic tests. When aspirated, most of the effusions prove to be sterile. If recovery is delayed and neurologic signs persist, a succession of aspirations is required. In our experience and that of others, patients in whom meningitis is complicated by subdural effusions are no more likely to have residual neurologic signs and seizures than are those without effusions.

**Spinal Fluid Examination**

As already indicated, the lumbar puncture is an indispensable part of the examination of patients with the symptoms and signs of meningitis or of any patient in whom this diagnosis is suspected. Bacteremia is not a contraindication to lumbar puncture. If there is clinical evidence of a focal lesion with increased intracranial pressure, then CT scanning of the head or MRI, looking for a mass lesion, is a prudent first step, but in most cases this is not necessary and should not delay the administration of antibiotics. In an attempt to determine the utility of the CT scan performed prior to a lumbar puncture, Hasbun and colleagues were able to identify several clinical characteristics that were likely to be associated with an abnormality on the scan in patients with suspected meningitis; these included a recent seizure, coma or confusion, gaze palsy, and others. The more salient finding in our opinion was that only 30-day period of life. It poses a number of special problems. Infants, of course, cannot complain of headache, stiff neck may be absent, and one has only the nonspecific signs of a systemic illness—fever, irritability, drowsiness, vomiting, convulsions—and a bulging fontanel to suggest the presence of meningeal infection. Signs of meningeal irritation do occur, but only late in the course of the illness. A high index of suspicion and liberal use of the lumbar puncture needle are the keys to early diagnosis. Lumbar puncture is ideally performed before any antibiotics are administered for other neonatal infections. An antibiotic regimen sufficient to control a septicemia may allow a meningeal infection to smolder and to flare up after antibiotic therapy for the systemic infection has been discontinued.

A number of other facts about the natural history of neonatal meningitis are noteworthy. It is more common in males than in females, in a ratio of about 3:1. Obstetric abnormalities in the third trimester (premature birth, prolonged labor, premature rupture of fetal membranes) occur frequently in mothers of infants who develop meningitis in the first weeks of life. In our experience and that of others, patients in whom meningitis is complicated by subdural effusions are no more likely to have residual neurologic signs and seizures than are those without effusions.

**Spinal Fluid Examination**

As already indicated, the lumbar puncture is an indispensable part of the examination of patients with the symptoms and signs of meningitis or of any patient in whom this diagnosis is suspected. Bacteremia is not a contraindication to lumbar puncture. If there is clinical evidence of a focal lesion with increased intracranial pressure, then CT scanning of the head or MRI, looking for a mass lesion, is a prudent first step, but in most cases this is not necessary and should not delay the administration of antibiotics. In an attempt to determine the utility of the CT scan performed prior to a lumbar puncture, Hasbun and colleagues were able to identify several clinical characteristics that were likely to be associated with an abnormality on the scan in patients with suspected meningitis; these included a recent seizure, coma or confusion, gaze palsy, and others. The more salient finding in our opinion was that only 30-day period of life. It poses a number of special problems. Infants, of course, cannot complain of headache, stiff neck may be absent, and one has only the nonspecific signs of a systemic illness—fever, irritability, drowsiness, vomiting, convulsions—and a bulging fontanel to suggest the presence of meningeal infection. Signs of meningeal irritation do occur, but only late in the course of the illness. A high index of suspicion and liberal use of the lumbar puncture needle are the keys to early diagnosis. Lumbar puncture is ideally performed before any antibiotics are administered for other neonatal infections. An antibiotic regimen sufficient to control a septicemia may allow a meningeal infection to smolder and to flare up after antibiotic therapy for the systemic infection has been discontinued.

A number of other facts about the natural history of neonatal meningitis are noteworthy. It is more common in males than in females, in a ratio of about 3:1. Obstetric abnormalities in the third trimester (premature birth, prolonged labor, premature rupture of fetal membranes) occur frequently in mothers of infants who develop meningitis in the first weeks of life. The most significant factor in the pathogenesis of the meningitis is maternal infection (usually a urinary tract infection or puerperal fever of unknown cause). The infection in both mother and infant is most often due to gram-negative enterobacteria, particularly *E. coli*, and group B streptococci and less often to *Pseudomonas*, *Listeria*, *Staph. aureus* or *epidermidis* (formerly *albus*), and group A streptococci. Analysis of postmortem material indicates that in most cases infection occurs at or near the time of birth, although clinical signs of meningitis may not become evident until several days or a week later.

In infants with meningitis, one should be prepared to find a unilateral or bilateral sympathetic subdural effusion regardless of bacterial type. Young age, rapid evolution of the illness, low polymorphonuclear cell count, and markedly elevated protein in the CSF correlate to some extent with the formation of effusions, according to Snedeker and coworkers. Also, these attributes greatly increase the likelihood of the meningitis being associated with neurologic signs. Transillumination of the skull is the simplest method of demonstrating the presence of an effusion, but computed tomography (CT) and magnetic resonance imaging (MRI) are the definitive diagnostic tests. When aspirated, most of the effusions prove to be sterile. If recovery is delayed and neurologic signs persist, a succession of aspirations is required. In our experience and that of others, patients in whom meningitis is complicated by subdural effusions are no more likely to have residual neurologic signs and seizures than are those without effusions.
2 percent of 235 patients had a focal mass lesion that was judged a risk for lumbar puncture; many others had CT findings of interest, including some with diffuse mass effect. This study does not totally clarify the issue of the safety of lumbar puncture but it emphasizes that patients who lack major neurologic findings are unlikely to have findings on the scan that will preclude lumbar puncture. Any coagulopathy that is deemed a risk for hemorrhagic complication of lumbar puncture should be rapidly reversed if possible.

The dilemma concerning the risk of promoting transtentorial or cerebellar herniation by lumbar puncture, even without a cerebral mass, as indicated in Chaps. 2 and 17, has been settled in favor of performing the tap if there is a reasonable suspicion of meningitis. The highest estimates of risk come from studies such as those of Rennick, who reported a 4 percent incidence of clinical worsening among 445 children undergoing lumbar puncture for the diagnosis of acute meningitis; most series give a lower number. It must be pointed out that a cerebellar pressure cone (tonsillar herniation) may occur in fulminant meningitis independent of lumbar puncture; therefore the risk of the procedure is probably even less than usually stated.

The spinal fluid pressure is so consistently elevated (above 180 mmH2O) that a normal pressure on the initial lumbar puncture in a patient with suspected bacterial meningitis raises the possibility that the needle is partially occluded or the spinal subarachnoid space is blocked. Pressures over 400 mmH2O suggest the presence of brain swelling and the potential for cerebellar herniation. Many neurologists favor the administration of intravenous mannitol if the pressure is this high, but this practice does not provide assurance that herniation will be avoided.

A pleocytosis in the spinal fluid is diagnostic. The number of leukocytes ranges from 250 to 100,000 per cubic millimeter, but the usual number is from 1000 to 10,000. Occasionally, in pneumococcal and influenza meningitis, the CSF may contain a large number of bacteria but few if any neutrophils for the first few hours. Cell counts of more than 50,000 per cubic millimeter raise the possibility of a brain abscess having ruptured into a ventricle. Neutrophils predominate (85 to 95 percent of the total), but an increasing proportion of mononuclear cells is found as the infection continues for days, especially in partially treated meningitis. In the early stages, careful cytologic examination may disclose that some of the mononuclear cells are myelocytes or young neutrophils. Later, as treatment takes effect, the proportions of lymphocytes, plasma cells, and histiocytes steadily increase.

Substantial hemorrhage or substantial numbers of red cells in the CSF are uncommon in meningitis, the exceptions being anthrax meningitis (see Lanska) as well as certain rare viral infections (Hantavirus, Dengue fever, Ebola virus, etc.) and some cases of amebic meningoencephalitis.

The protein content is higher than 45 mg/dL in more than 90 percent of the cases; in most it falls in the range of 100 to 500 mg/dL. The glucose content is diminished, usually to a concentration below 40 mg/dL, or less than 40 percent of the blood glucose concentration (measured concomitantly or within the previous hour) provided that the latter is less than 250 mg/dL. However, in atypical or culture-negative cases, other conditions associated with a reduced CSF glucose should be considered. These include hypoglycemia from any cause; sarcoidosis of the CNS; fungal or tuberculous meningitis; and some cases of subarachnoid hemorrhage, meningeal carcinomatosis, chemically induced inflammation from crianiopharyngioma or teratoma, or meningeal glomus tumor.

Gram’s stain of the spinal fluid sediment permits identification of the causative agent in most cases of bacterial meningitis; pneumococci and *H. influenzae* are identified more readily than meningococci. Small numbers of gram-negative diplococci in leukocytes may be indistinguishable from fragmented nuclear material, which may also be gram-negative and of the same shape as bacteria. In such cases, a thin film of uncentrifuged CSF may lend itself more readily to morphologic interpretation than a smear of the sediment. The most common error in reading Gram-stained smears of CSF is the misinterpretation of precipitated dye or debris as gram-positive cocci or the confusion of pneumococci with *H. influenzae*. The latter organisms may stain heavily at the poles, so that they resemble gram-positive diplococci, and older pneumococci often lose their capacity to take a gram-positive stain.

Cultures of the spinal fluid, which prove to be positive in 70 to 90 percent of cases of bacterial meningitis, are best obtained by collecting the fluid in a sterile tube and immediately inoculating plates of blood, chocolate, and MacConkey agar; tubes of thioglycolate (for anaerobes); and at least one other broth. The advantage of using broth media is that large amounts of CSF can be cultured. The importance of obtaining blood cultures is mentioned below.

The problem of identifying causative organisms that cannot be cultured, particularly in patients who have received antibiotics, may be overcome by the application of several special laboratory techniques. One of these is counterimmunoelectrophoresis (CIE), a sensitive test that permits the detection of bacterial antigens in the CSF in a matter of 30 to 60 min. It is particularly useful in patients with partially treated meningitis, in whom the CSF still contains bacterial antigens but no organisms on a smear or grown in culture. Several more recently developed serologic methods, radioimmunoassay (RIA) and latex-particle agglutination (LPA), as well as an enzyme-linked immunosorbent assay (ELISA), may be even more sensitive than CIE. An argument has been made that these procedures are not cost-effective, since—in virtually all instances in which the bacterial antigen can be detected—Gram’s stain also shows the organism. Our sense is that the more expensive tests are of some assistance if Gram’s stain is difficult to interpret and one or more doses of antibiotics render the cultures negative. Gene amplification by the polymerase chain reaction (PCR) is the most recently developed and most sensitive technique. As it becomes more widely available in clinical laboratories, rapid diagnosis may be facilitated (Desorges; Naber), but the use of careful Gram-stained preparations still needs to be encouraged.

Measurements of chloride concentrations in the CSF are not very useful, but they are usually found to be low, reflecting dehydration and low serum chloride levels. In contrast, CSF lactate dehydrogenase (LDH), although infrequently measured, can be of diagnostic and prognostic value. A rise in total LDH activity is consistently observed in patients with bacterial meningitis; most of this is due to fractions 4 and 5, which are derived from granulocytes. Fractions 1 and 2 of LDH, which are presumably derived from brain tissue, are only slightly elevated in bacterial meningitis but rise sharply in patients who develop neurologic sequelae or later die. Lysozymal enzymes in the CSF—derived from leukocytes, meningeal cells, or plasma—may also be increased in meningitis, but the clinical significance of this observation is unknown. Levels of lactic acid in the CSF (determined by either gas chromatography or enzymatic analysis) are also elevated in both bacterial and fungal meningitides (above 35 mg/dL) and may be helpful in distinguishing these disorders from viral meningitides, in which lactic acid levels remain normal.
Other Laboratory Findings In addition to CSF cultures, blood cultures should be obtained because they are positive in 40 to 60 percent of patients with *H. influenzae*, meningococcal, and pneumococcal meningitis, and they may provide the only definite clue as to the causative agent. Routine cultures of the oropharynx are as often misleading as they are helpful, because pneumococci, *H. influenzae*, and meningococci are common inhabitants of the throats of healthy persons. In contrast, cultures of the nasopharynx may aid in diagnosis, though often not in a timely way; the finding of encapsulated *H. influenzae* or groupable meningococci may provide the clue to the etiology of the meningal infection. Conversely, the absence of such a finding prior to antibiotic treatment makes an *H. influenzae* and meningococcal etiology unlikely. The leukocyte count in the blood is generally elevated, and immature forms are usually present. Meningitis may be complicated after several days by severe hyponatremia, the result of inappropriate secretion of antidiuretic hormone (ADH).

Radiologic Studies In patients with bacterial meningitis, chest films are essential because they may disclose an area of pneumonitis or abscess. Sinus and skull films may provide clues to the presence of cranial osteomyelitis, paranasal sinusitis, mastoiditis, or cranial osteomyelitis, but these structures are better visualized on CT scans, which have supplanted conventional films in most cases. The CT scan is particularly useful in detecting lesions that erode the skull or spine and provide a route for bacterial invasion, such as tumors or sinus wall defects, as well as in demonstrating a brain abscess or subdural empyema. MRI with gadolinium enhancement may display the meningeal exudate and cortical reaction, and both types of imaging, with appropriate techniques, will demonstrate venous occlusions and adjacent infarctions.

Recurrent Bacterial Meningitis

This is observed most frequently in patients who have had some type of ventriculovenous shunting procedure for the treatment of hydrocephalus or who have an incompletely closed dural opening after surgery. When the origin of the recurrence is inapparent, one should always suspect a congenital neuroectodermal sinus or a fistulous connection between the nasal sinuses and the subarachnoid space. The fistula in these latter cases is more often traumatic than congenital in origin (e.g., a previous basilar skull fracture), although the interval between injury and the initial bout of meningitis may be several years. The site of trauma is in the frontal or ethmoid sinuses or the cribiform plate, and *Strep. pneumoniae* is the usual pathogen. Often it reflects the predominance of such strains in nasal carriers. These cases usually have a good prognosis; mortality is much lower than in ordinary cases of pneumococcal meningitis.

*CSF rhinorrhea* is present in most cases of posttraumatic meningitis, but it may be transient and difficult to find. Suspicion of its presence is raised by the recent onset of anosmia or by the occurrence of a watery nasal discharge that is salty to the taste and increases in volume when the head is dependent. One way of confirming the presence of a CSF leak is to measure the glucose concentration of nasal secretions; ordinarily they contain little glucose, but in CSF rhinorrhea the amount of glucose approximates that obtained by lumbar puncture (two-thirds of the serum value). The site of a CSF leak can sometimes be demonstrated by injecting a dye, radioactive albumin, or water-soluble contrast material into the spinal subarachnoid space and detecting its appearance in nasal secretions or its site of exit by CT scanning. This testing is best performed after the acute infection has subsided. Persistence of CSF rhinorrhea usually requires surgical repair.

Differential Diagnosis

The diagnosis of bacterial meningitis is not difficult provided that one maintains a high index of suspicion. *Febrile patients with lethargy, headache, or confusion of sudden onset—even those with low-grade fever—should generally be subjected to lumbar puncture if no alternative explanation for the state is evident. It is particularly important to recall the possibility of meningitis in drowsy, febrile, and septic patients in an intensive care unit when no obvious source of fever is apparent. Overwhelming sepsis itself, or the multiorgan failure that it engenders, may cause an encephalopathy, but if there is a meningitis, it is imperative, in deciding on the choice of antibiotics, to identify it early. The same can be said for the confused alcoholic patient. Too often the symptoms are ascribed to alcohol intoxication or withdrawal, or to hepatic encephalopathy, until examination of the CSF reveals a meningitis. Although this approach undoubtedly results in many negative spinal fluid examinations, it is preferable to the consequence of overlooking a bacterial meningitis. Viral meningitis (which is far more common than bacterial meningitis), subarachnoid hemorrhage, chemical meningitis (following lumbar puncture, spinal anesthesia, or myelography), and tuberculous, leptospirosis, sarcoid, and fungal meningoencephalitis enter into the differential diagnosis as well, as discussed in later sections.

A number of nonbacterial meningitides must be considered in the differential diagnosis when the meningitis recurs repeatedly and all cultures are negative. Included in this group are Epstein-Barr virus (EBV) infections; Behcet disease, which is characterized by recurrent oropharyngeal mucosal ulceration, uveitis, orchitis, and meningitis; so-called Mollaret meningitis, which consists of recurrent episodes of fever and headache in addition to signs of meningeal irritation (due in many cases to herpes simplex, as discussed in Chap. 33); and the Vogt-Koyanagi-Harada syndrome, in which recurrent meningitis is associated with iridocyclitis and depigmentation of the hair and skin. The CSF in these recurrent types may contain large numbers of lymphocytes or polymorphonuclear leukocytes but no bacteria, and the glucose content is not reduced (see discussion of chronic and recurrent meningitis on page 635). Carcinomatous and lymphomatous meningitis, discussed in Chap. 31, rarely present in the fulminant manner of bacterial meningitis, but sometimes they do, and the CSF formulas can be similar. Rarely, a fulminant case of cerebral angiitis or intravascular lymphoma will present with headache, fever, and confusion in conjunction with a meningeal inflammatory reaction.

The other intracranial suppurative diseases and their differentiation from bacterial meningitis are considered further on in this chapter.

Treatment

Bacterial meningitis is a medical emergency. The first therapeutic measures are directed to sustaining blood pressure and treating septic shock (volume replacement, pressor therapy). A premium is then placed on choosing an antibiotic that is known both to be bactericidal for the suspected organism and is able to enter the CSF in effective amounts. **Treatment should begin while awaiting the results of diagnostic tests** and may be altered later in accordance with the laboratory findings. Whereas penicillin formerly sufficed.
to treat almost all meningitides acquired outside the hospital, the initial choice of antibiotic has become increasingly complicated as resistant strains of menigitic bacteria have emerged. The selection of drugs to treat nosocomial infections also presents special difficulties.

In recent years, many reports have documented an increasing incidence of pneumococcal isolates that have a relatively high resistance to penicillin, reaching 50 percent in some European countries. Current estimates are that in some areas of the United States, 15 percent of these isolates are penicillin-resistant to some degree (most have a relatively low level of resistance). In the 1970s, H. influenzae type B strains producing beta-lactamase, which are resistant to ampicillin and penicillin, were recognized. Currently, 30 percent of H. influenzae isolates produce the beta-lactamase enzyme, but almost all remain sensitive to third- and fourth-generation cephalosporins (cefotaxime, cefoperazone, cefizoxime, etc.).

Recommendations for the institution of empiric treatment of meningitis have been reviewed by Quagliarello and Scheld and are summarized in modified form in Table 32-2. In children and adults, third-generation cephalosporins are probably the best initial therapy for the three major types of community-acquired meningitides. In areas with substantial or increasing numbers of high-level penicillin-resistant pneumococci, consideration should be given to adding vancomycin and rifampin until the susceptibility of the isolate is established. Ampicillin should be added to the regimen in cases of suspected Listeria meningitis. When serious allergy to penicillin and cephalosporins precludes their use, chloramphenicol is a suitable alternative.

Isolation from the blood or CSF of a highly resistant organism requires the use of ceftriaxone, with the addition of vancomycin and rifampin. N. meningitides, at least in the United States, remains highly susceptible to penicillin and ampicillin. Regional variations and ongoing antibiotic-induced changes in the infecting microorganisms underscore the need for constant awareness of drug resistance in the physician’s local area, especially in the case of pneumococcal infections. Throughout the course of treatment, it is necessary to have access to a dependable laboratory that can carry out rapid and detailed drug-resistance testing.

In cases of meningitis due to Staph. aureus, including those that occur after neurosurgery or major head injury, administration of vancomycin and cefepime is a reasonable first approach, the cefepime offering better activity against Staph. aureus than does cefazidime (both are poor for methicillin-resistant organisms). Once the sensitivity of the organism has been determined, therapy may have to be altered or may be simplified by using vancomycin or nafcillin alone. The recommended dosages of the major antibiotics are listed in Table 32-3, and the choice of antibiotic for the optimal treatment of specific bacterial isolates is given in Table 32-4.

### Duration of Therapy
Most cases of bacterial meningitis should be treated for a period of 10 to 14 days except when there is a persistent parameningeal focus of infection (otic or sinus origin). Antibiotics should be administered in full doses parenterally (preferably intravenously) throughout the period of treatment. Treatment failures with certain drugs, notably ampicillin, may be attributable to oral or intramuscular administration, resulting in inadequate concentrations in the CSF. Repeated lumbar punctures are not necessary to assess the effects of therapy as long as there is progressive clinical improvement. The CSF glucose may remain

**Key:** MIC = Minimal inhibitory concentration.

<sup>a</sup> Cefotaxime or ceftiraxone.

<sup>b</sup> Addition of an aminoglycoside should be considered.

<sup>c</sup> Addition of rifampin should be considered.

<sup>d</sup> Linezolid, quinupristan-dalfopristan, and daptomycin are newer alternatives for methicillin-resistant *Staphylococcus*, but few cases have been studied.

Low for many days after other signs of infection have subsided and should occasion concern only if bacteria are present in the fluid and the patient remains febrile and ill.

Prolongation of fever or the late appearance of drowsiness, hemiparesis, or seizures should raise the suspicion of subdural effusion, mastoiditis, sinus thrombosis, cortical vein or jugular phlebitis, or brain abscess; all require that therapy be continued for a longer period. Bacteriologic relapse after treatment is discontinued requires reinitiation of therapy.

**Corticosteroids** Early controlled studies demonstrated no beneficial effects of corticosteroids in the treatment of pyogenic meningitis. More recent studies have given another perspective of the therapeutic value of dexamethasone in children and adults with meningitis. In children, although mortality was not affected in the main study conducted by Lebel and colleagues, fever subsided more rapidly and the incidence of sensorineural deafness and other neurologic sequelae was reduced, particularly in those with *H. influenzae* meningitis. On these grounds, it is recommended that the treatment of childhood meningitis include dexamethasone in high doses (0.15 mg/kg four times daily for 4 days), instituted as soon as possible.

Despite conflicting results from earlier studies of corticosteroids in adults, the trial by deGans and van de Beck has persuasively demonstrated a reduction in mortality and improved overall outcome if dexamethasone 10 mg is given just before the first dose of antibiotics and every 6 h for 4 days. The improvement was largely in patients who were infected with pneumococcus. Seizures and coma were reduced in incidence as a result of the administration of corticosteroids, but neurologic sequelae, such as hearing loss, were not affected. Based on a number of smaller studies, authorities in the field of bacterial meningitis have endorsed the use of dexamethasone in the doses mentioned above only if they can be started before antibiotics, as in the main trial, and only in those with pneumococcal infection (see Tunkel and Scheld). They also advise against the use of the drug if there is septic shock. We favor the use of corticosteroids in cases with overwhelming infection at any age (very high CSF pressure or signs of herniation, high CSF bacterial count with minimal pleocytosis, and signs of acute adrenal insufficiency, i.e., the Waterhouse-Friderichsen syndrome).

**Other Forms of Therapy** There is no evidence that repeated drainage of CSF is therapeutically effective. In fact, increased CSF pressure in the acute phase of bacterial meningitis is largely a consequence of cerebral edema, in which case the lumbar puncture may predispose to cerebellar herniation. A second lumbar puncture to gauge the effectiveness of treatment is generally not necessary, but it may be of value if the patient is worsening without explanation. Mannitol and urea have been employed with apparent success in some cases of severe brain swelling with unusually high initial CSF pressures (400 mmHg). Acting as osmotic diuretics, these agents enter cerebral tissue slowly, and their net effect is to decrease brain water. However, neither mannitol nor urea has been studied in controlled fashion in the management of meningitis. An adequate but not excessive amount of intravenous normal saline (avoiding fluids with free water) should be given, and anticonvulsants should be prescribed when seizures are present. In children, particular care should be taken to avoid hyponatremia and water intoxication—potential causes of brain swelling.

Anticonvulsants need not be administered routinely but should...
be given if a seizure has occurred or there is evidence of cortical vein occlusion.

**Prophylaxis** All household contacts of patients with meningococcal meningitis should be protected with antibiotic treatment. The risk of secondary cases is small for adolescents and adults but ranges from 2 to 4 percent for those less than 5 years of age and is probably higher in the elderly. A single dose of ciprofloxacin is effective. An alternative is a daily oral dose of rifampin—600 mg every 12 h in adults and 10 mg/kg every 12 h in children—for 2 days suffices. If 2 weeks or more have elapsed since the index case was found, no prophylaxis is needed.

As mentioned, immunization against *H. influenzae* is steadily reducing the incidence of meningitis from this organism. Also, fortunately many institutions housing young adults, such as colleges and the military, have instituted programs of immunization against *N. meningitidis*.

**Prognosis**

Untreated, bacterial meningitis is usually fatal. The overall mortality rate of uncomplicated but treated *H. influenzae* and meningococcal meningitis has remained at about 5 percent for many years; in pneumococcal meningitis, the rate is considerably higher (approximately 15 percent). Fulminant meningococcemia, with or without meningitis, also has a high mortality rate because of the associated vasomotor collapse and infective shock associated with adrenocortical hemorrhages (Waterhouse-Friderichsen syndrome). A disproportionate number of deaths from meningitis occur in infants and in the aged. The mortality rate is highest in neonates, from 40 to 75 percent in several reported series, and at least half of those who recover show serious neurologic sequelae. In adults, the presence of bacteremia, coma, seizures, and a variety of concomitant diseases—including alcoholism, diabetes mellitus, multiple myeloma, and head trauma—all worsen the prognosis. The triad of pneumococcal meningitis, pneumonia, and endocarditis has a particularly high fatality rate.

It is often impossible to explain the death of a patient with meningitis or at least to trace it to a single specific mechanism. The effects of overwhelming infection, with bacteremia and hypotension or brain swelling and cerebellar herniation, are clearly implicated in some patients during the initial 48 h. These events may occur in bacterial meningitis of any etiology; however, they are more frequent in meningococcal and pneumococcal infection. Some of the deaths occurring later in the course of the illness are attributable to respiratory failure, often consequent to aspiration pneumonia.

It has been stated that relatively few adult patients who recover from meningococcal meningitis show residual neurologic defects, whereas such defects are encountered in at least 25 percent of children with *H. influenzae* meningitis and up to 30 percent of child and adults patients with pneumococcal meningitis. Kastenbauer and Pfister, reporting on 87 adults with pneumococcal meningitis, have emphasized that the mortality remains quite high (24 percent in their series) and that cerebral venous or arterial thrombosis occurred in almost a third of cases as discussed further on. They also had two patients with an associated myelitis. We have seen two instances of upper cervical cord infarction in bacterial meningitis; quadriaparesis and respiratory failure were the result of compression from descent of the cerebellar tonsils (Ropper and Kanis). As already discussed, the role of lumbar puncture in promoting this complication has not been clarified.

Among infants who survive *H. influenzae* meningitis, Ferry and coworkers, in a prospective study of 50 cases, found that about half were normal, whereas 9 percent had behavioral problems and about 30 percent had neurologic deficits (seizures or impairment of hearing, language, mentation, and motor function). In a report of a personal series of 185 children recovering from bacterial meningitis, Pomeroy and associates found that 69 were still not normal neurologically at the end of a month; however, at the end of a year, only 26 demonstrated neurologic abnormalities; 18 were left with a hearing deficit, 13 with late afibrile seizures, and 8 with multiple deficits. The presence of a persistent neurologic deficit was the only independent predictor of later seizures. Dodge and colleagues found that 31 percent of children with pneumococcal meningitis were left with persistent sensorineural hearing loss; for meningococcal and *H. influenzae* meningitis, the figures were 10.5 and 6 percent, respectively.

Cranial nerve palsies other than deafness tend to disappear after a few weeks or months. Deafness in these infections is due to suppurrative cochlear destruction or less often to the ototoxic effects of aminoglycoside antibiotics. Bacteria reach the cochlea mainly via the cochlear aqueduct, which connects the subarachnoid space to the scala tympani. This occurs quite early in the course of infection, hearing loss being evident within a day of onset of the meningitis; in about half such cases, the deafness resolves. Hydrocephalus is an infrequent complication that may become manifest months after treatment and then requires shunting if gait or mentation is affected. It may be difficult to determine on clinical grounds whether a residual state of imbalance is the result of hydrocephalus or of eighth nerve damage.

The acute complications of bacterial meningitis, the intermediate and late neurologic sequelae, and the pathologic basis of these effects are summarized in Table 32-1. Other aspects of current treatment have been well summarized by Lambert.

**ENCEPHALITIS DUE TO BACTERIAL INFECTIONS**

Quite apart from acute and subacute bacterial endocarditis, which may give rise to cerebral embolism and characteristic inflammatory reactions in the brain (see further on), there are several systemic bacterial infections that are complicated by a special type of encephalitis or meningoencephalitis. Three common ones are *Mycoplasma pneumoniae* infections, *Listeria monocytogenes* meningoencephalitis, and *Legionnaire disease*. Probably Lyme borreliosis should be included in this category, but it is more chronic and is described further on in this chapter with the spirochetal infections. The rickettsial encephalitides (particularly Q fever), which mimic bacterial meningoencephalitis, are also addressed later in the chapter. Cat-scratch disease is another rare cause of bacterial meningoencephalitis. Meningoencephalitis due to brucellosis occurs very rarely in the United States. Whipple disease, discussed below, which appears to be a focal invasion of the brain by a novel bacterium, is an oddity but also belongs in this category.

**Mycoplasma pneumoniae Infections** This organism, which causes 10 to 20 percent of all pneumonia, is associated with a number of neurologic syndromes. Guillain-Barré polyneuritis, cranial neuritis, acute myositis, aseptic meningitis, transverse myelitis, global encephalitis, seizures, cerebellitis, acute disseminated (post-infectious) encephalomyelitis, and acute hemorrhagic leukoencephalitis (Hurst disease) have all been reported in association with
mycoplasmal pneumonias or with serologic evidence of a recent infection (Westenfelder et al; Fisher et al; Rothstein and Kenny). We have observed several patients with striking cerebral, cerebellar, brainstem, or spinal syndromes incurred during or soon after a mycoplasmal pneumonia or tracheobronchitis. In addition to the cerebellitis, which is clinically similar to the illness that follows varicella, unusual encephalitic syndromes of choreoathetosis, seizures, delirium, hemiparesis, and acute brain swelling (Reye syndrome) have each been reported in a few cases. The incidence of these complications has been estimated as 1 in 1000 mycoplasmal infections, but it may approach 5 percent when more careful surveillance is carried out during epidemics. A severe prodromal headache has occurred in most of our cases. At the time of onset of the neurologic symptoms, there may be scant signs of pneumonia, and in some patients, only an upper respiratory syndrome occurs.

The mechanism of cerebral damage that complicates mycoplasmal infections has not been established, but recent evidence suggests that the organism is present in the CNS during the acute illness. To our knowledge, the organism has been cultured from the brain in only one fatal case, but PCR techniques have detected fragments of mycoplasmal DNA in the spinal fluid from several patients (Narita et al). In other instances, the nature of the neurologic complications and their temporal relationship to the mycoplasmal infection clearly suggest that secondary autoimmune factors are operative; i.e., that these are instances of postinfectious encephalomyelitis (a type of acute disseminated encephalomyelitis described in Chap. 36). Most of the patients with the infectious variety have recovered with few or no sequela, but rare fatalities are reported.

The CSF usually contains small numbers of lymphocytes and other mononuclear cells and an increased protein content. The diagnosis can be established by culture of the organism from the respiratory tract (which is difficult), by rising serum titers of complement-fixing IgG and IgM antibodies and cold agglutinin antibodies in the blood and CSF, or by specialized DNA detection techniques from the CSF.

**Treatment** Erythromycin and tetracycline derivatives reduce morbidity, mainly by eradicating the pulmonary infection, but the effects of antibiotics on the nervous system complications are not known.

**Listeria monocytogenes Infections** Meningoencephalitis from this organism is most likely to occur in immunosuppressed and debilitated individuals and is a well-known and occasionally fatal cause of meningitis in the newborn. Meningitis is the usual neurologic manifestation, but there are numerous recorded instances of an isolated focal bacterial infectious encephalitis, rarely with a normal CSF, most cases showing a pleocytosis that may be initially polymorphonuclear. Between 1929, when the organism was discovered, and 1962, when Gray and Killinger collected all the reported cases, it was noted that 35 percent of 467 patients had either meningitis or meningoencephalitis as the primary manifestation. The infection may take the form of a brainstem, or “rhombencephalitis”—more specifically, several days of headache, fever, nausea, and vomiting followed by asymmetrical cranial nerve palsies, signs of cerebellar dysfunction, hemiparesis, quadriaparesis, or sensory loss. Respiratory failure has been reported. Of 62 cases of Listeria brainstem encephalitis reported by Armstrong and Fung, 8 percent were in immunosuppressed patients, meningeal signs were present in only half the patients, and the spinal fluid often showed, misleadingly mild abnormalities. CSF cultures yielded Listeria in only 40 percent of cases (blood cultures were even more often normal). Consistent with our experience, the early CT scan was often normal; MRI, however, has revealed abnormal signals in the parenchyma of the brainstem. The monocytosis, which gives the organism its name, refers to the reaction in the peripheral blood in rabbits and has not been prominent in the blood or CSF of our cases. One of the patients described by Lechtenberg and coworkers had a proven brain abscess; other patients have had multiple small abscesses (Uldry et al). Judging from the clinical signs in some cases, the infection appears to affect both the brainstem parenchyma and the extra-axial portion of cranial nerves.

**Treatment** The treatment is ampicillin (1 g intravenously every 4 h) in combination with tobramycin (5 mg/kg intravenously in three divided doses daily). If the condition of the host is compromised, the outcome is often fatal; but most of our patients without serious medical disease have made a full and prompt recovery with treatment.

**Legionella** This potentially fatal respiratory disease caused by the gram-negative bacillus Legionella pneumophila, first came to medical notice in July 1976, when a large number of members of the American Legion fell ill at their annual convention in Philadelphia. The fatality rate was high. In addition to the obvious pulmonary infection, manifestations referable to the CNS and other organs were observed regularly. Lees and Tyrrell described patients with severe and diffuse cerebral involvement, and Baker et al and Shetty et al described others with cerebellar and brainstem syndromes. The clinical details have varied. One constellation consisted of headache, obtundation, acute confusion or delirium with high fever, and evidence of pulmonary distress; another took the form of tremor, nystagmus, cerebellar ataxia, extracranial muscle and gaze palsies, and dysarthria. Other neurologic abnormalities have been observed, such as inappropriate ADH secretion, or a syndrome of more diffuse encephalomyelitis or transverse myelitis, similar to that observed with Mycoplasma infections. The CSF is usually normal and CT scans of the brain are negative, a circumstance that makes diagnosis difficult. The neuropathologic abnormalities have not been studied. Suspicion of the disease, based on suspected exposure or on the presence of an atypical pneumonia, should prompt tests for serum antibodies to the bacillus, which rise to high levels in a week to 10 days. In most patients the signs of CNS disorder resolve rapidly and completely, although residual impairment of memory and a cerebellar ataxia have been recorded. To date, the Legionella bacillus has not been isolated from the brain or spinal fluid.

**Treatment** Treatment in adults has consisted of erythromycin, 0.5 to 1.0 g intravenously q 6 h for a 3-week period. The combination of the erythromycin analogue azithromycin and ciprofloxacin (a quinolone) is believed to be more potent.

**Cat-Scratch Encephalitis** Reports of approximately 100 cases of encephalitis from cat-scratch disease have appeared in the medical literature. The causative organism is a gram-negative bacillus now called Rochalimaea henselae (formerly Bartonella henselae). The illness begins as unilateral axillary or cervical adenopathy occurring after a seemingly innocuous scratch (rarely a bite) from an infected cat. The cases with which we are familiar began with an encephalopathy and high fever (higher temperature than with most of the other organisms that are capable of causing a bacterial encephalitis), followed by seizures or status epilepticus. The organism has also been implicated in causing a focal cerebral vasculitis in
AIDS patients as well as neuroretinitis in both immunocompromised and immune-competent patients. Demonstration of elevated complement-fixing titers and detection of the organism by PCR or by silver staining from an excised lymph node are diagnostic. A single high antibody titer is inadequate for this purpose.

**Treatment** Erythromycin, chloramphenicol, or doxycycline seem to eradicate the infection; macrolide antibiotics have been recommended in recalcitrant cases. Most patients recover completely, but one of our patients and a few reported by others have died.

**Anthrax** This rare form of meningoencephalitis is included here because of the current interest in *Bacillus anthracis* as a weapon of warfare. Lanska was able to collect from the literature 70 patients with meningococcal infection, most of whom were encephalopathic. He has estimated that fewer than 5 percent of infected individuals will acquire a meningoencephalitis; in the 2001 U.S. outbreak, only 1 of 11 cases with anthrax pneumonitis developed this complication. Reflecting the main site of natural infection, the majority of cases originated in cutaneous anthrax. In addition to a typically fulminating course after a prodrome of one or several days, the exceptional feature was a hemorrhagic and inflammatory spinal fluid formula. Subarachnoid hemorrhage was prominent in autopsy material, reflecting presumably necrosis of the vessel wall as a toxic effect of *B. anthracis*. Although natural isolates are sensitive to penicillin, bioengineered strains are resistant; therefore combined treatment with rifampin, vancomycin, and either ciprofloxacin or doxycycline has been recommended initially. The benefit of specific antitoxin is uncertain once meningoencephalitis has occurred.

**Brucellosis** This worldwide disease of domesticated livestock is frequently transmitted to humans in areas where the infection is enzootic. In the United States, it is distinctly rare, with 200 cases or less being reported annually since 1980. During the 1950s it was a fashionable explanation for chronic fatigue. In the Middle East, infection with *Brucella* is still frequent, attributable to the ingestion of raw milk. In Saudi Arabia, for example, al Deeb and coworkers reported on a series of 400 cases of brucellosis, of which 13 presented with brain involvement (acute meningoencephalitis, papilledema and increased intracranial pressure, and meningoencephalitic manifestations). The CSF showed a lymphocytic pleocytosis and increased protein content. Blood and CSF antibody titers to the organism were greater than 1/640 and 1/128, respectively. Protracted treatment with rifampin, cotrimoxazole, and doxycycline suppressed the infection.

**Whipple Disease** This is a rare but often discussed disorder, predominantly of middle-aged men. Weight loss, fever, anemia, statorrhoea, abdominal pain and distention, arthralgias, lymphadenopathy, and hyperpigmentation are the usual systemic manifestations. Less often, infection is associated with a number of neurologic syndromes. It is now known to be caused by a gram-positive bacillus, *Tropheryma whippelii*, which resides predominantly in the gut. Biopsy of the jejunal mucosa, which discloses macrophages filled with the periodic acid–Schiff (PAS)-positive organisms, is diagnostic. PAS-positive histiocytes have also been identified in the CSF as well as in periventricular regions, in the hypothalamic and tuberal nuclei, or diffusely scattered in the brain.

The neurologic manifestations most often take the form of a slowly progressive memory loss or dementia of subacute or early chronic evolution. Supranuclear ophthalmoplegia, ataxia, seizures, myoclonus, nystagmus, and a highly characteristic oculomotoric movement described as myorhythmia (which looks more to us like rhythmic myoclonus) have been noted less often than the deforming syndrome. The rhythmic myoclonus or spasm occurs in synchronous bursts involving several adjacent regions, mainly the eyes, jaw, and face. Almost always the myorhythmias are accompanied by a supranuclear vertical gaze paresis that sometimes affects horizontal eye movements as well. Presumably, the neurologic complications are the result of infiltration of the brain by the organism, but this has not been satisfactorily established.

Approximately half of the patients have a mild pleocytosis and some of these have PAS-positive material in the CSF. A variety of brain imaging abnormalities have been recorded, none characteristic, but either enhancing focal lesions or a normal scan may be found. The diagnosis is made mainly from PAS staining of an intestinal (jejunal) biopsy, as already mentioned, supplemented by PCR testing of the bowel tissue or biopsy material from brain or lymph node. In cases of subacute progressive limb and gait ataxia occurring in middle-aged or older men in whom no cause is uncovered by less invasive means, it is justifiable to perform these tests (see Chap. 5). Rarely, the neurologic symptoms may occur in the absence of gastrointestinal disease (Adams et al). In the extensive review of 84 cases by Louis and colleagues, 71 percent had cognitive changes, half with psychiatric features; 31 percent had myoclonus; 18 percent, ataxia; and 20 percent had the oculomotoric and skeletal myorhythmias that are virtually pathognomonic of Whipple disease (Schwartz et al).

**Treatment** A course of penicillin and streptomycin followed by trimethoprim-sulfamethoxazole or ceftriaxone and continued for 1 year is one of the currently recommended treatment regimens. An alternative approach is 2 weeks of ceftriaxone followed by treatment with trimethoprim-sulfamethoxazole or a tetracycline for a year. Antibiotic-resistant cases and instances of relapse after antibiotic treatment are known. The review by Anderson may be consulted for details.

**Acute Toxic Encephalopathy** Lyon and colleagues described “acute encephalopathy of obscure origin in children,” a febrile and sometimes fatal illness that could not be ascribed to direct infection of the nervous system. During the height of a systemic bacterial or sometimes viral infection, the child sinks into coma, seizures are infrequent, the neck is supple, and the spinal fluid shows no changes or only a few cells. This is undoubtedly an illness of diverse causes, among them fluid overload and electrolyte imbalance, Reye syndrome (page 969), and, possibly most common, postinfectious encephalitis. Nonetheless, cases continue to be reported, such as those of Thi and colleagues, which can only be classified as a noninfectious bacterial encephalopathy or encephalitis. A relationship to the “septic encephalopathy” of adults, which has been emphasized by the group from London, Ontario, is possible but unproved. The term acute toxic encephalopathy still has some utility in these cases, but a careful search for better-characterized causes of febrile coma must be undertaken.

**SUBDURAL EMPYEMA**

Subdural empyema is an intracranial (rarely intraspinal) supplicative process between the inner surface of the dura and the outer surface of the arachnoid. The term subdural abscess, among others, has been applied to this condition, but the proper name is empyema, indicating suppuration in a preformed space. Contrary to prevailing
Symptomatology and Laboratory Findings

Usually the history which probably accounts for the unilateral seizures and other signs to begin on the sides of the veins nearest the subdural exudate. The cytes, and mononuclear cells. The thrombi in cerebral veins seem arachnoid with small numbers of neutrophilic leukocytes, lympho-
on the inner surface of the dura and infiltration of the underlying hemisphere is depressed, and in fatal cases there is often an ipsilateral temporal lobe herniation. Microscopic ex-
derived cerebral hemisphere is confined there; occasionally it is found in the posterior fossa, cov-
other cranial structures. In infants and children and in children and in-
frequently in adults, there may be spread from a leptomeningitis. Infection gains entry to the subdural space by direct extension through bone and dura or by spread from septic thrombosis of the venous sinuses, particularly the superior longitudinal sinus. Rarely, the subdural infection is metastatic, from infected lungs; hardly ever is it secondary to bacteremia or septicemia. Occasionally it extends from a brain abscess.

It is again of interest that cases of sinus origin predominate in adolescent and young adult men (Kaufman et al). In such cases, streptococci (nonhemolytic and viridans) are the most common organisms, followed by anaerobic streptococci (often Strep. milleri) or Bacteroides. Less often Staph. aureus, E. coli, Proteus, and Pseudomonas are causative. In about half the cases unrelated to surgery, no organisms can be cultured or seen on Gram’s stain. The factors that lead to a subdural empyema rather than to a cerebral abscess are not fully understood.

Pathology

A collection of subdural pus, in quantities ranging from a few milliliters to 100 to 200 mL, lies over the cerebral hemisphere. Pus may spread into the interhemispheric fissure or be confined there; occasionally it is found in the posterior fossa, covering the cerebellum. The arachnoid, when cleared of exudate, is cloudy, and thrombosis of meningeal veins may be seen. The underlying cerebral hemisphere is depressed, and in fatal cases there is often an ipsilateral temporal lobe herniation. Microscopic ex-
amination discloses various degrees of organization of the exudate on the inner surface of the dura and infiltration of the underlying arachnoid with small numbers of neutrophilic leukocytes, lymphocytes, and mononuclear cells. The thrombi in cerebral veins seem to begin on the sides of the veins nearest the subdural exudate. The superficial layers of the cerebral cortex undergo ischemic necrosis, which probably accounts for the unilateral seizures and other signs of disordered cerebral function (Kubik and Adams).

Symptomatology and Laboratory Findings

Usually the history includes reference to chronic sinusitis or mastoiditis with a recent flare-up causing local pain and increase in purulent nasal or aural discharge. In sinus cases, the pain is over the brow or between the eyes; it is associated with tenderness on pressure over these parts and sometimes with orbital swelling. General malaise, fever, and headache—at first localized, then severe and generalized and associated with vomiting—are the first indications of intracranial spread. They are followed in a few days by drowsiness and increasing stupor, rapidly progressing to coma. At about the same time, focal neurologic signs appear, the most important of which are unilateral motor seizures, hemiplegia, hemianesthesia, aphasia, and paralysis of lateral conjugate gaze. Fever and leukocytosis are always present and the neck is stiff. Cases that follow surgery may be more indolent.

The usual CSF findings are an increased pressure, pleocytosis in the range of 50 to 1000 per cubic millimeter, a predominance of polymorphonuclear cells, elevated protein content (75 to 300 mg/ dL), and normal glucose values. The fluid is often sterile, but on occasion an organism is cultured. If the patient is stuporous or comatose, there is a risk in performing a lumbar puncture, and one should proceed first with other diagnostic procedures.

By CT scanning one can see the ear or sinus lesions or bone erosion. The meninges around the empyema enhance and the collection of pus can be visualized more dependably with MRI. Em-
pyema that follows meningitis tends to localize on the undersurface of the temporal lobe and may require coronal views in order to be well visualized.

Several conditions must be distinguished clinically from sub-
dural empyema—a treated subacute bacterial meningitis, cerebral thrombophlebitis, brain abscess (see further on), herpes simplex encephalitis (page 638), acute necrotizing hemorrhagic leukoen-
cephalitis (page 792), and septic embolism due to bacterial endocar-
ditis (see further on in this chapter).

Treatment

Most subdural empyemas, by the time they are rec-
ognized clinically, require immediate drainage through multiple enlarged frontal bur holes or through a craniotomy in cases with an interhemispheric, subtemporal, or posterior fossa location. The surgical procedure should be coupled with appropriate antibiotic therapy, which consists in most cases of the intravenous adminis-
tration of 20 to 24 million units of penicillin per day plus a third-
generation cephalosporin and metronidazole. Bacteriologic find-
ings or an unusual presumed source may dictate a change to different drugs, particularly to later-generation cephalosporins. Without such massive antimicrobial therapy and surgery, most patients will die, usually within 7 to 14 days. On the other hand, patients who are treated promptly may make a surprisingly good recovery, including full or partial resolution of their focal neuro-
logic deficits.

As with certain small brain abscesses, small subdural collect-
ions of pus that are recognized by CT scanning or MRI before stupor and coma have supervened may respond to treatment with large doses of antibiotics alone. The resolution (or lack thereof) of the empyema can be readily followed by repeated imaging of the brain (Leys et al).

CRANIAL EPIDURAL ABSCESS

This condition is almost invariably associated with osteomyelitis in a cranial bone and originates from an infection in the ear or paranasal sinuses or from a surgical procedure, particularly if the frontal sinus or mastoid had been opened or a foreign device inserted. Rarely, the infection is metastatic or spreads outward from a dural sinus thrombophlebitis. Pus and granulation tissue accu-
mulate on the outer surface of the dura, separating it from the cran-
ial bone. The symptoms are those of a local inflammatory process: frontal or auricular pain, purulent discharge from sinuses or ear, and fever and local tenderness. Sometimes the neck is slightly stiff. Localizing neurologic signs are usually absent. Rarely, a focal sei-
zure may occur, or the fifth and sixth cranial nerves may be in-
volved with infections of the petrous part of the temporal bone. The CSF is usually clear and under normal pressure but may con-
tain a few lymphocytes and neutrophils (20 to 100 per millilitre) and a slightly increased amount of protein. Treatment consists of antibiotics aimed at the appropriate pathogen(s)—often Staph. au-
reus. Later, the diseased bone in the frontal sinus or the mastoid, from which the extradural infection had arisen, may have to be removed and the wound packed to ensure adequate drainage. Re-
results of treatment are usually good.
Spinal Epidural and Subdural Abscesses These types of abscess possess unique clinical features and constitute important neurologic and neurosurgical emergencies. They are discussed in Chap. 44 with other diseases of the spinal column and spinal cord.

**INTRACRANIAL SEPTIC THROMBOPHLEBITIS**

The dural sinuses drain blood from all of the brain into the jugular veins. The largest and most important of these, and the ones usually involved by infection, are the lateral (transverse), cavernous, petrous, and, less frequently, the longitudinal (sagittal) sinuses. A complex system of lesser sinuses and cerebral veins connects these large sinuses to one another as well as to the diploic and meningeal veins and veins of the face and scalp. The basilar venous sinuses are contiguous to several of the paranasal sinuses and mastoid cells.

Usually there is evidence that thrombophlebitis of the large dural sinuses has extended from a manifest infection of the middle ear and mastoid cells, the paranasal sinuses, or skin around the upper lip, nose, and eyes. Other forms of intracranial suppuration frequently complicate these cases, including meningitis, epidural abscess, subdural empyema, and brain abscess. Occasionally, infection may be introduced by direct trauma to large veins or dural sinuses. A variety of organisms, including all the ones that ordinarily inhabit the paranasal sinuses and skin of the nose and face, may give rise to intracranial thrombophlebitis. Streptococci and staphylococci are the ones most often incriminated. With the exception of fever and poorer outcome, the syndromes associated with septic lateral sinus phlebitis are similar to those produced by bland thrombosis of the veins, as discussed in Chap. 34, on cerebrovascular diseases.

**Septic Lateral (Transverse) Sinus Thrombophlebitis** In lateral sinus thrombophlebitis—which usually follows chronic infection of the middle ear, mastoid, or petrous bone—earache and mastoid tenderness are succeeded, after a period of a few days to weeks, by generalized headache and, in some instances, papilledema. If the thrombophlebitis remains confined to the transverse sinus, there are no other neurologic signs. Spread to the jugular bulb may give rise to the syndrome of the jugular foramen (see Table 47-1) and involvement of the torcular, leading to increased intracranial pressure. One lateral sinus, usually the right, is larger than the other, which may account for greatly elevated pressure when it is occluded. Contiguous involvement of the superior sagittal sinus causes seizures and focal cerebral signs (see below). Fever, as in all forms of septic intracranial thrombophlebitis, tends to be present but intermittent, and other signs of the septic state may be prominent. Infected emboli may be released into the bloodstream, causing petechiae in the skin and mucous membranes and pulmonary sepsis. The CSF is usually normal but may show a small number of cells and a modest elevation of protein content.

Imaging by MR and CT has supplanted cerebral venography, arteriography, and the various older tests involving compression of the jugular veins in the diagnosis of venous sinus thrombosis. MRI sequences that are appropriate to the slow blood flow in the cerebral venous system must be selected and imaging planes carefully chosen to pass through the venous sinuses. CT and MRI at the same time are able to detect abscess and hydrocephalus.

Prolonged administration of high doses of antibiotics is the mainstay of treatment. Anticoagulation, shown to be beneficial in aseptic venous occlusion, is still of uncertain value, but it is usually administered as well (see Chap. 34).

**Septic Cavernous Sinus Thrombophlebitis** This condition is usually secondary to infections of the ethmoid, sphenoid, or maxillary sinuses or the skin around the eyes and nose, sometimes originating in a seemingly innocuous lesion. Occasionally, no antecedent infection can be recognized. In addition to headache, high fluctuating fever, and signs of systemic toxicity, there are characteristic local effects. Obstruction of the ophthalmic veins leads to chemosis, proptosis, and edema of the ipsilateral eyelids, forehead, and nose. The retinal veins become engorged, and this may be followed by retinal hemorrhages and papilledema. More often, however, vision in the affected eye is lost by a yet undefined type of optic neuropathy as noted below, without visible alterations in the fundus. Involvement of the third, fourth, sixth, and ophthalmic division of the fifth cranial nerves, which lie in the lateral wall of the cavernous sinus (Fig. 34-32), leads to ptosis, varying degrees of ocular palsy, pain around the eye, and sensory loss over the forehead. Within a few days, spread through the circular sinus to the opposite cavernous sinus results in bilateral symptoms. The posterior part of the cavernous sinus may become infected via the superior and inferior petrosal veins without the occurrence of orbital edema or ophthalmoplegia but usually with abducens and facial paralysis. The CSF is usually normal unless there is an associated meningitis or subdural empyema.

The only effective therapy in the fulminant variety, associated with thrombosis of the anterior portion of the sinus, is the administration of high doses of antibiotics aimed at coagulase-positive staphylococci and probably gram-negative pathogens as well. As with septic lateral sinus phlebitis, anticoagulants have been used, but their value has not been proved. In our cases, the cranial nerve palsies have resolved to a large extent, but visual loss, if it occurs, tends to remain, with findings suggestive of infarction of the retroorbital portion of the optic nerve; the mechanism of this complication is not clear. Cavernous sinus thrombosis must be differentiated from mucormycosis infection of the sinuses and orbital cellulitis, which usually occur in patients with uncontrolled diabetes, and from other fungus infections (notably *Aspergillus*), carcinomatous invasion of the sphenoid bone, and sphenoid wing meningioma.

**Septic Thrombosis of the Superior Sagittal (Longitudinal) Sinus** This may be asymptomatic, but more often there is a clinical syndrome of headache, unilateral convulsions, and motor weakness, first on one side of the body, then on the other, due to extension of the thrombophlebitis into the superior cerebral veins. Papilledema and increased intracranial pressure almost always accompany these signs. Severe generalized and vertex headache is a typical complaint in the awake patient. Because of the localization of function in the cortex that is drained by the sinus, the weakness may take the form of a cural (lower limb) monoplegia or, less often, of a paraplegia. A corticosenory loss may occur in the same distribution. Homonymous hemianopia or quadrantanopia, aphasia, paralysis of conjugate gaze, and urinary incontinence (in bilateral cases) have also been observed.

As in the case of aseptic thrombosis, loss of the flow void in the superior sagittal sinus in the MRI is diagnostic, and the clot may be visualized if the correct imaging sequences are used. A similar change can be seen on axial images of the contrast-enhanced CT scan by altering the viewing windows so as to show the clot within the posterior portion of the sagittal sinus. The CT
portion of the brain is infected via the venous route. The spread of infectious phlebitis of the pial veins and dural sinuses, by infarcting brain tissue, renders the latter more vulnerable to invasion by infected material and the creation of abscesses derived from them. Abscesses are frequently multiple, in contrast to otogenic and rhinogenic abscesses (Fig. 32-1). Also, almost all deep cerebral abscesses—for example, those within the thalamus—have a systemic source. It should also be noted that the clinical and radiologic features of a solitary abscess may mimic those of a brain tumor.

In regard to brain abscess, careful distinction should be made between the neuropathologic effects of subacute and acute bacterial endocarditis. Subacute bacterial endocarditis (SBE), i.e., the type caused by the implantation of streptococci of low virulence (alpha and gamma streptococci) or similar organisms on valves previously damaged by rheumatic fever or on a patent ductus arteriosus or ventricular septal defect, seldom gives rise to a brain abscess. The cerebral lesions of SBE are due to embolic occlusion of vessels by fragments of vegetations and bacteria, which cause infarction of brain tissue and a restricted inflammatory response around the involved blood vessels and the overlying meninges (“cerebritis”). The cerebral symptoms of a stroke may be the first clinical manifestations of the disease. The SBE contains a moderate number of polymorphonuclear leukocytes and frequently red cells as well, but the glucose content is not lowered and suppuration in the brain or in the subarachnoid space does not occur. It is theorized that the chronicity of the streptococcal infection allows the body to develop immunity to the organisms. The meningeal pleocytosis is occasionally associated with headache, stiff neck, and rarely with alterations of consciousness. Over time, the inflamed artery may form an aneurysm (mycotic aneurysm) that later gives rise to paranchymal or subarachnoid hemorrhage (see page 727).

In contrast, the more fulminating acute bacterial endocarditis—i.e., the type caused by Staph. aureus, hemolytic streptococcus, gram-negative organisms, or the pneumococcus (organisms that may involve previously normal valves)—frequently gives rise to multiple small abscesses in the brain and other organs of the body. Purulent meningitis may also develop, or there may be infarcts or meningoencephalorrhages and, infrequently, ruptured mycotic aneurysms. Rarely do the miliary abscesses progress to large ones, as illustrated in Fig. 32-1. Rapidly evolving cerebral signs in patients with acute endocarditis (delirium, confusion, mild focal cerebral signs) are nearly always caused by embolic infarction or hemorrhage. It should be mentioned that anticoagulation has not been shown to reduce the incidence of embolization from endocarditis. In patients with endocarditis on a prosthetic heart valve, anticoagulation may be continued, but cautiously, and this treatment is suspended if there is a hemorrhagic brain infarction.

It is estimated that about 5 percent of cases of congenital heart defect lead to abscess formation.
Enteric organisms are almost always associated with otitic infections; are usually a consequence of accidental or surgical trauma; tend to vary with the source of the abscess; staphylococcal abscesses are associated with congenital heart disease; are rarely seen before the third year of life. The tetralogy of Fallot is by far the most common anomaly implicated, but the abscesses may occur with any right-to-left intracardiac or pulmonary shunt that allows venous blood returning to the heart to enter the systemic circulation without first passing through the lungs. Pulmonary emboli, by increasing the back pressure in the right heart, may open (make patent) an occult foramen ovale. A pulmonary arteriovenous malformation has a similar effect. Nearly half of the reported cases of pulmonary arteriovenous fistulas also have Osler-Rendu-Weber telangiectasia and neurologic symptoms. When the filtering effect of the lungs is thus circumvented, pyogenic bacteria or infected emboli from a variety of sources may gain access to the brain, where, aided by the effects of venous stasis and perhaps of infarction, an abscess is established. At least this is the current theory of its mechanism.

**Etiology** The most common organisms causing brain abscess are streptococci, many of which are anaerobic or microaerophilic. These organisms are often found in combination with other anaerobes, notably Bacteroides and Propionibacterium (diphtheroids), and may be combined with Enterobacteriaceae, such as E. coli and Proteus. Staphylococci also commonly cause brain abscess, but pneumococci, meningococci, and H. influenzae rarely do. In addition, the gram-positive higher bacteria Actinomyces and Nocardia and certain fungi discussed later—notably Candida, Mucor, and Aspergillus—are isolated in some cases. The type of organism tends to vary with the source of the abscess; staphylococcal abscesses are usually a consequence of accidental or surgical trauma; enteric organisms are almost always associated with otitic infections; and anaerobic streptococci are commonly metastatic from the lung and paranasal sinuses. The organisms associated with acute bacterial endocarditis have been mentioned above. Predisposing to nocardial brain abscess is pulmonary nocardial infection, often in immunosuppressed patients; this diagnosis is doubtful without a pneumonic infiltrate. Thus knowledge of the site of the abscess and the antecedent history enables one to institute appropriate therapy while awaiting the results of bacterial and fungal cultures.

**Pathology** Localized inflammatory exudate, septic thrombosis of vessels, and aggregates of degenerating leukocytes represent the early reaction to bacterial invasion of the brain. Surrounding the necrotic tissue are macrophages, astroglia, microglia, and many small veins—some of which show endothelial hyperplasia, contain fibrin, and are cuffed by polymorphonuclear leukocytes. There is interstitial edema in the surrounding white matter. At this stage, which is rarely observed postmortem, the lesion is poorly circumscribed and tends to enlarge by a coalescence of inflammatory foci. The term cerebritis is loosely applied to this local suppurative encephalitis or immature abscess.

Within several days, the intensity of the reaction begins to subside and the infection tends to become delimited. The center of the abscess takes on the character of pus; at the periphery, fibroblasts proliferate from the adventitia of newly formed blood vessels and form granulation tissue, which is readily identified within 2 weeks of the onset of the infection. As the abscess becomes more chronic, the granulation tissue is replaced by collagenous connective tissue. It has also been noted, both in experimental animals and in humans, that the capsule of the abscess is not of uniform thickness, frequently being thinner on its medial (paraventricular) aspect. These factors account for the propensity of cerebral abscesses to spread deeply into the white matter and to produce daughter abscesses or a chain of abscesses and extensive surrounding cerebral edema. In some instances the process culminates in a catastrophic rupture into the ventricles.

**Figure 32-1.** A. Multiple brain abscesses associated with bacterial endocarditis (Staphylococcus aureus) in a 55-year-old man. The large abscess in the left hemisphere shows a characteristic ring enhancement. B. Contrast-enhanced CT scan 4 months after institution of antibiotic treatment. The abscesses have resolved.
Clinical Manifestations  Headache is the most frequent initial symptom of intracranial abscess. Other early symptoms, roughly in order of their frequency, are drowsiness and confusion; focal or generalized seizures; and focal motor, sensory, or speech disorders. Fever and leukocytosis are not consistently present, depending on the phase of the development of the abscess at the time of presentation (see below). In patients who harbor chronic ear, sinus, or pulmonary infections, a recent activation of the infection frequently precedes the onset of cerebral symptoms. In patients without an obvious focus of infection, headache or other cerebral symptoms may appear abruptly on a background of mild general ill health or congenital heart disease. In some patients, bacterial invasion of the brain may be asymptomatic or may be attended only by a transitory focal neurologic disorder, as might happen when a septic embolus lodges in a brain artery. Sometimes stiff neck accompanies generalized headache, suggesting the diagnosis of meningitis (especially a partially treated one).

These early symptoms may improve in response to antimicrobial agents, but within a few days or weeks, recurrent headache, slowness in mentation, focal or generalized convulsions, and obvious signs of increased intracranial pressure provide evidence of an inflammatory mass in the brain. Localizing neurologic signs become evident sooner or later, but, like papilledema, they occur relatively late in the course of the illness. However, as stated above, some patients present only with focal neurologic signs.

The nature of the focal neurologic defect will, of course, depend on the location of the abscess. In temporal lobe abscess, headache in the early stages is usually on the same side as the abscess and is localized to the frontotemporal region. If the abscess lies in the dominant temporal lobe, there is characteristically an anomic aphasia. An upper homonymous quadrantanopia may be demonstrable owing to interruption of the inferior portion of the optic radiation. This may be the only sign of abscess of the right temporal lobe; contralateral motor or sensory defects in the limbs tend to be minimal, though weakness of the lower face is often observed.

In frontal lobe abscess, headache, drowsiness, inattention, and general impairment of mental function are prominent. Contralateral hemiparesis with motor seizures and a motor disorder of speech (with dominant hemisphere lesions) are the most frequent neurologic signs. An abscess of the parietal lobe will give rise to a series of characteristic but sometimes subtle focal disturbances (page 400). The main manifestation of an occipital lobe lesion is a homonymous hemianopia. All of the aforementioned focal signs may be obscured by inattention, drowsiness, and stupor, and one must be persistent in searching for them. When abscesses are multiple and widely distributed in the cerebral and cerebellar hemispheres, the ultimate syndrome is unpredictable; but most often, in our experience, it has taken the form of a global encephalopathy, like that of a metabolic confusional state, with a subtle hemiparesis or seizure.

In cerebellar abscess, headache in the postauricular or suboccipital region is usually the initial symptom and may at first be ascribed to infection in the mastoid cells. Coarse nystagmus, weakness of conjugate gaze to the side of the lesion, cerebellar ataxia of the ipsilateral arm and leg, and ataxia of gait are the usual signs. The ataxia may be difficult to demonstrate if the patient is very ill and cannot sit up or walk. As a general rule, the signs of increased intracranial pressure are more prominent with cerebellar abscesses than with cerebral ones. Mild contralateral or bilateral corticospinal tract signs are often misleading, being evidence of brainstem compression or hydrocephalus rather than a frontal lobe lesion. In the late stages, consciousness becomes impaired as a result of direct compression of the upper brainstem or from hydrocephalus; both are ominous signs.

Although slight fever is characteristic of the early invasive phase of cerebral abscess, the temperature may return to normal as the abscess becomes encapsulated. The same is true of leukocytosis. The sedimentation rate is usually elevated. In the early stages of abscess formation, the CSF pressure is moderately increased; the cell count ranges from 20 to 300 per cubic millimeter, occasionally higher or lower, with 10 to 80 percent neutrophils; and the protein content is modestly elevated, rarely more than 100 mg/dL. Glucose values are not lowered and the CSF is sterile unless there is a concomitant bacterial meningitis. As already mentioned, the combination of brain abscess and acute bacterial meningitis occurs only rarely. However, in some patients abscess is combined with subdural empyema; in these instances the clinical picture can be very complicated, although headache, fever, and focal signs again predominate. In a small number of cases, especially partially treated ones, there are no spinal fluid abnormalities and the sedimentation rate may be normal.

It is apparent from this overview that the clinical picture of brain abscess is far from stereotyped. Whereas headache is the most prominent feature in most patients, seizures or certain focal signs may predominate in others, and a considerable number of patients will present with only signs of increased intracranial pressure. In some instances the symptoms evolve swiftly over a week, new ones being added day by day. In others, the invasive stage of cerebral infection is inconspicuous, and the course is so indolent that the entire clinical picture does not differ from that of malignant brain tumor. In such cases the abscess may become apparent only when cerebral imaging performed for the evaluation of headache or other symptoms discloses a ring-enhancing mass. Even then, the radiologic distinction between tumor and abscess is not straightforward, depending often on the presence of a uniform, enhancing capsule that is typical of a mature abscess (see below.) Another impressive feature of cerebral abscess is the unpredictability with which the symptoms may evolve, particularly in children. Thus, a patient whose clinical condition seems to have stabilized may, in a matter of hours or a day or two, advance to an irreversible state of coma. Often this is due to rupture of the abscess into the subarachnoid or ventricular CSF.

Diagnosis  CT and MRI are the most important diagnostic procedures. In the CT scan, the capsule of the abscess enhances and the center of the abscess and surrounding edematous white matter are hypodense (Fig. 32-1). With MRI, in T1-weighted images, the capsule enhances and the interior of the abscess is hypointense; in T2-weighted images, the surrounding edema is apparent and the capsule is hypointense. Suppurative encephalitis (cerebritis) appears as dot-sized areas of decreased density that enhance with gadolinium. Practically all abscesses larger than 1 cm produce positive scans. There is almost no likelihood of cerebral abscess if enhanced CT and MRI studies are negative. Blood cultures, sedimentation rate and chest x-ray are indispensable in the complete diagnosis of brain abscess, although it must be acknowledged that blood cultures are likely to be unrevealing except in cases of acute endocarditis.

If there is no apparent source of infection and there are only signs and symptoms of a mass lesion, the differential diagnosis includes tuberculosis or fungal abscess, glioma, metastatic carcinoma, toxoplasmosis, subdural hematoma, subacute infarction of...
factory results are obtained if the patient lapses into coma before treatment is started; more than 50 percent of such patients in the past have died. If treatment is begun while the patient is alert, the mortality is in the range of 5 to 10 percent, and even multiple metastatic abscesses may respond. About 30 percent of surviving patients are left with neurologic residua. Of these, focal epilepsy is the most troublesome. Following successful treatment of a cerebral abscess in a patient with congenital heart disease, correction of the cardiac anomaly is indicated to prevent recurrence. One may consider closing a patent foramen ovale if no other explanation for the abscess is apparent.

**SUBACUTE AND CHRONIC FORMS OF MENINGITIS**

There are many infectious processes that induce an inflammation of the leptomeninges of lesser intensity and more chronicity than the acute forms described above. Included here are some bacterial and most mycotic infections, tuberculosis, syphilis, Lyme disease, human immunodeficiency virus (HIV) infection, and presumed noninfectious causes, such as lymphoma, sarcoidosis, Wegener granulomatosis, and others. As pointed out by Ellner and Bennett (their experience coincides with that of Swartz and our own), the clinical syndrome comprises cognitive disorders, seizures, and absence of lateralizing and focal cerebral signs, with or without headache and mild stiffness of the neck. In some cases there is little or no fever or other manifestation of infection. As with acute bacterial meningitis, the CSF will usually divulge the causative agent, but not so readily as in acute bacterial meningitis, since the organisms are usually by nature more difficult to detect and culture. The main identifiable forms of subacute and chronic meningitis are described below. The approach to the complicated problem of chronic meningitis (aseptic variety) in which no cause can be found is addressed in Chap. 33, which should be referred to along with this section.

**Tuberculous Meningitis**

In the United States and in most western countries, the incidence of tuberculous meningitis, which parallels the frequency of systemic tuberculosis, has until recently decreased steadily since the Second World War. At the Cleveland Metropolitan General Hospital, for example, the incidence of tuberculous meningitis during the years 1959 to 1963 was between 4.4 and 8.4 per 10,000 admissions (a decade earlier it was 5.8 to 12.9 per 10,000 admissions). By contrast, at the K. E. M. Hospital in Bombay during the period 1961 to 1964, the incidence of this disease (in children) was 400 per 10,000 admissions, and similar figures have been reported from other parts of India. Since 1985, however, there has been a moderate increase in the incidence of systemic tuberculosis (and tuberculous meningitis) in the United States—a 16 percent annual increase compared to an average annual decline of 6 percent during the preceding 30 years (Snider and Roper). This increase is due mainly though not exclusively to the HIV epidemic. In fact, tuberculosis may be the first clinical manifestation of HIV infection (Barnes et al); among patients with full-blown AIDS, the incidence of tuberculosis is almost 500 times the incidence in the general population (Pitchenik et al). In developing countries, particularly in sub-Saharan Africa, recent estimates of the incidence of tuberculosis suggest that it is 25 times more frequent than in the United States, again largely because of the prevalence of HIV infection.
Pathogenesis  Tuberculous meningitis is usually caused by the acid-fast organism *Mycobacterium tuberculosis* and exceptionally by *Mycobacterium bovis* or *Mycobacterium fortuitum*. The emergence of AIDS has led to a marked increase in cases caused by both the classic organism and also by these last two atypical mycobacteria. Rich described two stages in the pathogenesis of tuberculous meningitis—first a bacterial seeding of the meninges and subpial regions of the brain with the formation of tubercles, followed by the rupture of one or more of the tubercles and the discharge of bacteria into the subarachnoid space. Whether the meningitis always originates in this way is, in our opinion, unlikely. It can be said, however, that the meningitis may occur as a terminal event in cases of miliary tuberculosis or as part of generalized tuberculosis with a single focus (tuberculoma) in the brain.

Pathologic Findings  Small, discrete white tubercles are scattered over the base of the cerebral hemispheres and to a lesser degree on the convexities. The brunt of the pathologic process falls on the basal meninges, where a thick, gelatinous exudate accumulates, obliterating the pontine and interpeduncular cisterns and extending to the meninges around the medulla, the floor of the third ventricle and subthalamic region, the optic chiasm, and the undersurfaces the temporal lobes (Fig. 32-2). By comparison, the convexities are little involved, possibly because the associated hydrocephalus obliterates the cerebral subarachnoid space. Microscopically, the meningeal tubercles are like those in other parts of the body, consisting of a central zone of caseation surrounded by epithelioid cells and some giant cells, lymphocytes, plasma cells, and connective tissue. The exudate is composed of fibrin, lymphocytes, plasma cells, other mononuclear cells, and some polymorphonuclear leukocytes. The ependyma and choroid plexus are studded with minute glistening tubercles. The exudate also surrounds the spinal cord. Unlike the pyogenic meningitides, the disease process is not confined to the subarachnoid space but frequently penetrates the pia and ependyma and invades the underlying brain, so that the process is truly a *meningoencephalitis*.

Other pathologic changes depend on the chronicity of the disease process and recapitulate the changes that occur in the subacute and chronic stages of the pyogenic meningitides (Table 32-1). Cranial nerves are often involved by the inflammatory exudate as they traverse the subarachnoid space—indeed, far more often than with typical bacterial meningitis. Arteries may become inflamed and occluded, with infarction of brain. Blockage of the basal cisterns frequently results in a meningeal obstructive tension type of hydrocephalus. Marked ependymitis with blocking of the CSF in the aqueduct or fourth ventricle is a less common cause. The exudate may predominate around the spinal cord, leading to multiple spinal radiculopathies and compression of the cord.

Clinical Features  Tuberculous meningitis occurs in persons of all ages. Formerly it was more frequent in young children, but now it is more frequent in adults, at least in the United States. The early manifestations are usually low-grade fever, malaise, headache (more than one-half the cases), lethargy, confusion, and stiff neck (75 percent of cases), with Kernig and Brudzinski signs. Characteristically, these symptoms evolve less rapidly in tuberculous than in bacterial meningitis, usually over a period of a week or two, sometimes longer. In young children and infants, apathy, hyperirritability, vomiting, and seizures are the usual symptoms; however, stiff neck may not be prominent or may be absent altogether. Because of the inherent chronicity of the disease, signs of cranial nerve involvement (usually ocular palsies, less often facial palsies or deafness) and papilledema may be present at the time of admission to the hospital (in 20 percent of the cases). Occasionally the disease may present with the rapid onset of a focal neurologic deficit due to hemorrhagic infarction, with signs of raised intracranial pressure or with symptoms referable to the spinal cord and nerve roots. Hypothermia and hyponatremia have been additional presenting features in several of our cases.

In approximately two-thirds of patients with tuberculous meningitis there is evidence of active tuberculosis elsewhere, usually in the lungs and occasionally in the small bowel, bone, kidney, or ear. In some patients, however, only inactive pulmonary lesions are found, and in others there is no evidence of tuberculosis outside of the nervous system. In the previously mentioned Cleveland series, which comprised 35 patients, active pulmonary tuberculosis was found in 19, inactive in 6, and involvement of the nervous system alone in 9; only 2 of the 35 patients had nonreactive tuberculin tests (Hinman), somewhat different from the general experience noted below. Among our adult patients, tuberculous meningitis is now seen almost exclusively in those with AIDS, in alcoholics, and in immigrants from the Far East and India. One recent case with an atypical organism occurred in an otherwise healthy local professor who spent several months in East Africa. Except for the emergence of drug-resistant organisms, the HIV infection does not appear to change the clinical manifestations or the outcome of tuberculous meningitis. However, others disagree, insisting that the course of the bacterial infection is accelerated in AIDS patients, with more frequent involvement of organs other than the lungs.

If the illness is untreated, its course is characterized by confusion and progressively deepening stupor and coma, coupled with cranial nerve palsies, pupillary abnormalities, focal neurologic deficits, raised intracranial pressure, and decerebrate postures; invariably, a fatal outcome then follows within 4 to 8 weeks of the onset.

*Figure 32-2.* MRI in tuberculous meningitis. There is gadolinium enhancement of the basal meninges, reflecting intense inflammation that is accompanied by hydrocephalus and cranial nerve palsies.
Laboratory Studies  Again, the most important is the lumbar puncture, which preferably should be performed before the administration of antibiotics. The CSF is usually under increased pressure and contains between 50 and 500 white cells per cubic millimeter, rarely more. Early in the disease there may be a more or less equal number of polymorphonuclear leukocytes and lymphocytes; but after several days, lymphocytes predominate in the majority of cases. In some cases, however, *M. tuberculosis* causes a persistent polymorphonuclear pleocytosis, the other usual causes of this CSF formula being *Nocardia, Aspergillus*, and *Actinomyces* (Peacock). One of our patients, a museum guard who spent all his time among Egyptian artifacts, manifested a persistent polymorphonuclear response due to *M. fortuitum*. The protein content of the CSF is always elevated, between 100 to 200 mg/dL in most cases, but much higher if the flow of CSF is blocked around the spinal cord. Glucose is reduced to levels below 40 mg/dL but rarely to the very low values observed in pyogenic meningitis; the glucose falls slowly and a reduction may become manifest only several days after the patient has been admitted to the hospital. The serum sodium and chloride and CSF chloride are often reduced, in most instances because of inappropriate ADH secretion or an Addisonian state due to tuberculosis of the adrenals. Most children with tuberculous meningitis have positive tuberculin skin tests (85 percent), but the rate is far lower in adults with or without AIDS: 40 to 60 percent in most series.

The conventional methods of demonstrating tubercle bacilli in the spinal fluid are inconsistent and often too slow for immediate therapeutic decisions. Success with the traditional identification of tubercle bacilli in smears of CSF sediment stained by the Ziehl-Neelsen method is a function not only of their number but also of the persistence with which they are sought. There are effective means of culturing the tubercle bacilli; but since their quantity is usually small, attention must be paid to proper technique. The amount of CSF submitted to the laboratory is critical; the more that is cultured, the greater the chances of recovering the organism. Unless one of the newer techniques is utilized, growth in culture media is not seen for 3 to 4 weeks. PCR, by DNA amplification, permits the detection of small amounts of tubercle bacilli and is now widely available for clinical use. There is also a rapid culture technique that allows identification of the organisms in less than 1 week. However, even these new diagnostic methods may give uncertain results or take several days to demonstrate the organism, and they cannot be counted on to exclude the diagnosis. For these reasons, if a presumptive diagnosis of tuberculous meningitis has been made and cryptococcosis and other fungal infections and meningeal neoplasia have been excluded, treatment should be instituted immediately, without waiting for the results of bacteriologic study.

Other diagnostic procedures (CT, MRI) may be necessary in patients who present with or develop raised intracranial pressure, hydrocephalus, or focal neurologic deficits. One or more tuberculomas may also be visualized (see below). MR angiography may demonstrate vascular occlusive disease from granulomatous infiltration of the walls of arteries of the circle of Willis and their primary branches.

**Other Forms of Central Nervous System Tuberculosis**

**Tuberculous Serous Meningitis**  This condition, which is essentially a self-limited meningitis, is observed with some frequency in countries where tuberculosis is prevalent. The CSF shows a modest pleocytosis in some but not all cases, a normal or elevated protein content, and normal glucose levels. Headache, lethargy, and confusion are present in some cases and there are mild meningeal signs. Lincoln, who was the first to call attention to this syndrome, believed it to be a meningeal reaction to an adjacent tuberculous focus that did not progress to a frank meningitis. This form of meningitis is not always self-limited.

**Tuberculomas**  These are tumor-like masses of tuberculous granulation tissue, most often multiple but also occurring singly, that form in the parenchyma of the brain and range from 2 to 12 mm in diameter (Fig. 32-3). The larger ones may produce symptoms of a space-occupying lesion and periventricular ones may cause obstructive hydrocephalus, but many are unaccompanied by symptoms of focal cerebral disease. In the United States tuberculomas are rarities; but in developing countries they constitute from 5 to 30 percent of all intracranial mass lesions. In some tropical countries, cerebellar tuberculomas are the most frequent intracranial tumors in children. Because of their proximity to the meninges, the CSF often contains a small number of lymphocytes and increased protein (serous meningitis), but the glucose level is not reduced. True tuberculous abscesses of the brain are rare except in AIDS patients. In two of our patients who presented with a brainstem tuberculoma, there was a serous meningitis that progressed to a fatal generalized tuberculous meningitis.

**Myeloradiculitis**  The spinal cord may be affected in a number of ways in the course of tuberculous infection. In addition to compressing spinal roots and cord, causing spinal block, the inflammatory meningeal exudate may invade the underlying parenchyma, producing signs of posterior and lateral column and spinal root disease. Spinal cord symptoms may also accompany tuberculous osteomyelitis of the spine with compression of the cord by an epidural abscess, a mass of granulation tissue (Pott paraplegia), or, less frequently, by the mechanical effects of angulation of the ver-

---

Tebral column. Pott disease, a tuberculous osteomyelitis of the spine that leads to compression of vertebral bodies and a highly characteristic kyphotic deformity at the thoracic or upper lumbar level, is discussed in Chap. 44.

Treatment of Tuberculous Meningitis

The treatment of tuberculous meningitis consists of the administration of a combination of drugs—isoniazid (INH), rifampin (RMP), and a third and sometimes a fourth drug, which may be ethambutal (EMB), ethionamide (ETA), or preferably pyrazamide (PZA). All of these drugs have the capacity to penetrate the blood-brain barrier, with INH, ETA, and PZA ranked higher than the others in this respect. Resistant strains of tuberculous organisms are emerging, which require the use of PZA and ETA in addition to the two main drugs (INH and RMP). It has been pointed out that immigrants from certain countries (e.g., Vietnam, Haiti, Philippines) have high rates of INH-resistant organisms. Antibiotics must be given for a prolonged period, 18 to 24 months as a general rule (although it may not be necessary to give all three or four drugs for the entire period).

Isoniazid is the single most effective drug. It can be given in a single daily dose of 5 mg/kg in adults and 10 mg/kg in children. Its most important adverse effects are neuropathy (see page 1133) and hepatitis, particularly in alcoholics. Neuropathy can be prevented by the administration of 50 mg pyridoxine daily. In patients who develop the symptoms of hepatitis or have abnormal liver function tests, INH should be discontinued. The usual dose of RMP is 600 mg daily for adults, 15 mg/kg for children. Ethambutal is given in a single daily dose of 15 mg/kg. The dosage of ETA is 15 to 25 mg/kg daily for adults; because of its tendency to produce gastric irritation, it is given in divided doses, after meals. The latter two drugs (EMB and ETA) may cause optic neuropathy, so that patients taking them should have regular examinations of visual acuity and red-green color discrimination. Pyrazamide is given once daily in doses of 20 to 35 mg/kg. Rash, gastrointestinal disturbances, and hepatitis are the main adverse effects. Except for INH, all these drugs can be given only orally or by stomach tube. Isoniazid may be given parenterally, in the same dosage as with oral use. Corticosteroids may be used in patients whose lives are threatened by the effects of subarachnoid block or raised intracranial pressure, and only in conjunction with antituberculous drugs. It should be noted that in a randomized study conducted in Vietnam, including patients with and without AIDS, the addition of intravenous dexamethasone (0.4 mg/kg daily for a week and then tapering doses for 3 weeks) reduced mortality from 41 percent to 32 percent but had no effect on residual disability (Thwaites et al).

Intracranial tuberculoma calls for a similar course of antibiotics, as outlined above. Under the influence of these drugs, the tuberculum(s) may decrease in size and small ones ultimately disappear or calcify, as judged by the CT scan; if they do not, and especially if there is “mass effect,” excision may be necessary. Patients with spinal osteomyelitis or localized granulomas with spinal cord compression (Pott paraplegia) should also be explored surgically after an initial course of chemotherapy, and an attempt should be made to excise the tuberculous focus. We have, however, dealt successfully with tuberculous osteomyelitis of the cervical spine (without significant abscess or cord compression) by immobilizing our patient in a hard collar and administering triple-drug therapy (at the suggestion of the patient’s father, who was a physician in India), once it was established that the spinal column was stable.

The overall mortality of patients with CNS tuberculosis is still significant (about 10 percent), infants and the elderly being at greatest risk. Among HIV-infected patients, the mortality from tuberculous meningitis is considerably higher (21 percent in the series of Berenguer et al)—the result of delays in diagnosis and, more importantly, of resistance to antituberculous drugs in some patients (Snider and Roper) (see also page 1061). Early diagnosis, as one might expect, enhances the chances of survival. In patients who are treated late in the disease, when coma has supervened, the mortality rate is nearly 50 percent. Between 20 and 30 percent of survivors manifest a variety of residual neurologic sequelae, the most important of which are diminished intellectual function, psychiatric disturbances, recurrent seizures, visual and oculomotor disorders, deafness, and hemiparesis. A detailed account of these has been given by Wasz-Hockert and Donner.

Sarcoidosis

The infectious etiology of sarcoidosis has never been established, but the disease may suitably be considered at this point because of its close resemblance pathologically and clinically to tuberculosis and other granulomatous infections. Indeed, one still credible theory of causation considers sarcoidosis to be a modified form or product of the tubercle bacillus. This has not been proved, and the same can be said for various other infectious and noninfectious etiologies that from time to time have been proposed as the underlying cause. Current opinion favors the idea that sarcoidosis represents an exaggerated cellular immune response to a limited class of antigens or autoantigens (Crystal).

The essential lesion in sarcoidosis consists of focal collections of epithelioid cells surrounded by a rim of lymphocytes; frequently there are giant cells, but caseation is lacking. The sarcoid tubercles may be found in all organs and tissues including the peripheral and CNS, but the most frequently involved are the mediastinal and peripheral lymph nodes, lungs, liver, skin, phalangeal bones, eyes, and parotid glands.

Sarcoidosis is accompanied by nervous system involvement (neurosarcoidosis) in approximately 5 percent of cases according to the worldwide surveys of Delaney and of Siltzbach and colleagues. It may take any one of several forms. As indicated in Chaps. 13, 46 and 47, isolated sarcoid granulomas may involve peripheral or cranial nerves, giving rise to a subacute or chronic neuritis or plexopathy of asymmetrical type (Jefferson). Polaneuritis may occur but is rare; Zuniga and colleagues have summarized our own experience. Of the cranial nerves, the facial is the most frequently involved, either as part of the uveoparotid syndrome (Heerfordt syndrome) or independently. The facial palsy may be unilateral or bilateral; if the latter, the nerves may be affected simultaneously or in succession. The occurrence of hyperacusis indicates that the lesion is central to the stylomastoid foramen. Blindness may follow basal infiltration that encompasses the optic nerves (Fig. 32-4).

CNS sarcoidosis is said to be infrequent, but we encounter one or more cases yearly. Several syndromes are known that are due to localized involvement of the meninges, brain, and spinal cord (Table 32-5). In Scadding’s series of 275 patients, only 3 developed CNS lesions; in other large series, the incidence of CNS involvement was greater, but most are in the range of 5 to 10 percent (10 of 145 patients studied by Mayock et al; 14 of 285, by Chen and McLeod; and 33 of 649, by Stern et al). Delaney, in his review of the literature, found the neurologic involvement in sar-

Sarcoidosis can be equally divided between the peripheral and central nervous systems. There is also a well-described myopathy associated with sarcoidosis; it is discussed below and also considered in Chap. 49; the neuropathy of sarcoidosis is discussed in Chap. 46.

In the CNS, sarcoidosis takes the form of a granulomatous infiltration of the meninges and underlying parenchyma, most frequent at the base of the brain (Fig. 32-4). The process is subacute or chronic in nature, mimicking other granulomatous lesions and neoplasms. One particular syndrome that has been associated with sarcoid consists of a circumscribed lesion of the stalk of the pituitary gland, optic chiasm, and hypothalamus, causing visual disturbances, polydipsia, polyuria, or somnolence. Hydrocephalus, seizures, cranial nerve palsies, and corticospinal and cerebellar signs are other occasional manifestations. Rarely sarcoid can be a cause of a chronic recurrent meningitis, or severe, steroid-responsive headache. Granulomas may present as a mass or as one or more focal infiltrating cortical and subcortical lesions that tends to follow the course of superficial cortical veins. Focal cerebral signs, including seizures, due presumably to large focal deposits of sarcoid in the brain, are observed. Among the focal syndromes reported have been an amnestic or dementing condition from infiltration of the medial temporal lobes and psychotic and related behavioral aberrations.

The spinal meninges and spinal cord may be infiltrated, usually independently of brain involvement, imparting a picture of adhesive arachnoiditis or an inflammatory myelopathy. There is more prominent focal contrast enhancement and T2 signal abnormality on MRI than is usual for a demyelinating disease. Characteristic of the spinal lesion is enhancement on the surface of the cord and a degree of expansion at the level of the myelitic lesion (page 1060). We have had experience with several such cases in which the only evidence of sarcoid was a lesion in the thoracic cord; in the absence of systemic manifestations of sarcoid. Biopsy of the spinal cord lesion, a risky procedure, was necessary for diagnosis in 2 cases.

A slight lymphocytic pleocytosis (10 or up to 200 cells per cubic millimeter) and a moderate increase in protein content and gamma globulin (generally without oligoclonal bands), consistent with meningeal involvement, are the usual CSF findings, but many cases show no change. The glucose content is normal or slightly reduced. The spinal form may be associated with CSF block and greatly raised protein content, the result of enlargement of the cord or adhesive arachnoiditis.

The diagnosis of CNS sarcoidosis is made on the basis of the clinical features together with clinical and biopsy evidence of sarcoid granulomas in other tissues (lymph nodes, lungs, bones, uvea, skin, and muscle). The contrast-enhanced CT scan is a useful means of detecting meningeal involvement, and MRI may disclose periventricular and white matter lesions, although the latter pattern is usually not specific. Nodular or streak-like perivenular enhance-
ment may be found on the contrast-enhanced MRI, as described by Sherman and Stern and by Christoforidis et al. The intensity of enhancement may be reduced after the administration of corticosteroids for several days. There is indeed a wide variety of changes that has been described on MRI. Positron emission tomography may be helpful by demonstrating increased activity that corresponds to a brain or cord lesion and also by revealing increased activity at the site of involved pulmonary lymph nodes. Radionuclide scanning with gallium-67 shows uptake in the chest, spleen, salivary or lacrimal glands in almost half of patients and can be a useful ancillary test.

Test material for the formerly popular Kveim-Siltzbach skin reaction (a homogenate of spleen or lymph node from patients with known sarcoid) is no longer generally available. It has also been found that sarcoid can give rise to a noncaseating epithelioid granuloma at the site of a Mantoux test (for tuberculosis) placed on the skin of the forearm (a skin biopsy is necessary to demonstrate it), but we do not know the validity of this test. The latency in development of the granuloma (up to 6 weeks), during which time corticosteroids cannot be given, and a limited rate of positivity (less than two-thirds of patients) also reduce this test’s usefulness (see Mankodi et al). Delayed hypersensitivity skin reactions to other antigens are frequently depressed. Mild anemia, lymphocytopenia (occasional eosinophilia), slightly elevated sedimentation rate, hypercalcemia, and hyperglobulinemia are common findings in active disease. Serum levels of angiotensin-converting enzyme (ACE) are increased in two-thirds of the patients but seem to us to be less helpful in the diagnosis of CNS involvement. It is not clear if the concentration of ACE in the spinal fluid is expected to be increased in CNS sarcoid. Obviously, evidence of primary sarcoidosis in the mediastinum and lungs should be sought in these cases by chest x-ray and CT scan.

The differential diagnosis of what has been termed “neurosarcoidosis” is quite broad and includes multiple sclerosis as well as a number of other entities such as Sjögren syndrome, systemic lupus, lymphoma, isolated angitis of the CNS, intravascular lymphoma, leprosy, cryptococcosis and other fungal infections that cause abscesses and meningitis, toxoplasmosis, brucellosis, syphilis, Wegener granulomatosis, and, of course, tuberculosis.

**Treatment** Administration of corticosteroids is the main therapy, but it has not been subjected to scrutiny in an adequate trial. Cyclosporine can be used when the patient cannot tolerate steroids or as an adjunctive treatment to reduce the dose of steroid. Other immunosuppressive drugs have not proved to be as effective; methotrexate, cyclophosphamide, chloroquine, and radiation of focal lesions have found favor in various clinics, but again, the results are difficult to judge. The major problem is in knowing when to treat the patient, because the disease may remit spontaneously in about half the cases. The recent onset of neurologic symptoms, indicating an active phase of the disease, or a disabling syndrome such as myelopathy are the most certain indications for steroid therapy. One approach is to use prednisone in divided daily doses of 40 mg, given for 2 weeks, followed by 2-week periods in which the dose is reduced by 5 mg, until a maintenance dose of 20 to 10 mg on alternate days is reached. Therapy should be continued for at least 6 months and in many cases is required for several years.

**Neurosyphilis**

The incidence of neurosyphilis, like that of CNS tuberculosis, declined dramatically in the decades following World War II, with the advent of penicillin. In the United States, for instance, the rate of first admissions to mental hospitals because of neurosyphilis fell from 4.3 per 100,000 population (in 1946) to 0.4 per 100,000 (in 1960). However, in more recent years, the number of reported cases of early syphilis has increased, both in nonimmunocompromised individuals and particularly in HIV-infected ones. One may logically anticipate an increase in late syphilis, including neurosyphilis, as these patients live longer. Notable also is the shift in clinical presentation of neurosyphilis from parenchymal damage, now quite rare, to one of chronic meningovascular disease, particularly in patients with AIDS. Congenital syphilis represents a special problem, which is discussed with developmental diseases in Chap. 37.

**Etiology and Pathogenesis** Syphilis is caused by *Treponema pallidum*, a slender, spiral, motile organism. The biologic characteristics of this organism and the natural history of the disease it produces are described in *Harrison’s Principles of Internal Medicine*, which may be consulted as an introduction to the following discussion. In this chapter, only the basic facts regarding the neurosyphilitic infection are enumerated. The following ones have been well established by clinical and postmortem observation; without knowing them, it is not possible to treat patients with syphilis intelligently (Fig. 32-5).

1. The treponeme usually invades the CNS within 3 to 18 months of inoculation with the organism. If the nervous system is not involved by the end of the second year, as shown by completely negative CSF, there is only 1 chance in 20 that the patient will develop neurosyphilis as a result of the original infection; if the CSF is negative at the end of 5 years, the likelihood of developing neurosyphilis falls to 1 percent.

2. The initial event in the neurosyphilitic infection is a meningitis, which occurs in about 25 percent of all cases of syphilis. Usually the meningitis is asymptomatic and can be discovered only by lumbar puncture. Exceptionally, it is more intense and causes cranial nerve palsies, seizures, apoplectic phenomena (due to associated vascular lesions), and symptoms of increased intracranial pressure. As a corollary, the occurrence of these symptoms in a young adult should always suggest the possibility of neurosyphilis and requires examination of the CSF.

3. This meningitis may persist in an asymptomatic state and ultimately, after a period of years, may lead to parenchymal damage. In some cases, however, there is a natural subsidence of the meningitis—a spontaneous regression.

4. All forms of neurosyphilis begin as a meningitis, and a more or less active meningeal inflammation is the invariant accompaniment of all forms of neurosyphilis. The early clinical syndromes are meningitis and meningovascular syphilis; the late ones are vascular syphilis (1 to 12 years), followed later by general paresis, tabes dorsalis, optic atrophy, and meningomyelitis. The latter are pathologic sequences that result from chronic syphilitic meningitis. The intermediate pathologic stages—whether by transformation of a persistent asymptomatic syphilitic meningitis or a relapsing meningitis to the late forms of parenchymal neurosyphilis—are unknown.

5. From a clinical point of view, asymptomatic neurosyphilis is the most important form of neurosyphilis. If all cases of asymptomatic neurosyphilis were discovered and adequately
CHAPTER 32 INFECTIONS OF THE NERVOUS SYSTEM AND SARCOIDOSIS

615

Figure 32-5. Diagram of the evolution of neurosyphilis.

treated, the symptomatic varieties would in most instances be prevented. Since asymptomatic neurosyphilis can be recognized only by the changes in the CSF, it is axiomatic that all patients with syphilis should have a spinal fluid examination.

6. Clinical syndromes such as syphilitic meningitis, meningo-vascular syphilis, general paresis, tabes dorsalis, optic atrophy, and meningo(myelitis are abstracts ions, which at autopsy seldom exist in pure form. Since all of them appear to have a common origin in a meningitis, there is usually a combination of two or more syndromes, e.g., meningitis and vascular syphilis, tabes and paresis, etc. Even though the patient’s symptoms may have been referable to only one part of the nervous system, postmortem examination usually discloses diffuse changes, in both brain and spinal cord, which were of insufficient severity to be detected clinically.

7. The clinical syndromes and pathologic reactions of congenital syphilis are similar to those of the late acquired forms, differing only in the age at which they occur. All the aforementioned biologic events are equally applicable to congenital and childhood neurosyphilis.

8. The CSF is a sensitive indicator of the presence of active neurosyphilitic infection. The CSF abnormalities consist of (a) a pleocytosis of up to 100 cells per cubic millimeter, sometimes higher, mostly lymphocytes and a few plasma cells and other mononuclear cells (the counts may be lower in patients with AIDS and those with leukopenia); (b) elevation of the total protein, from 40 to 200 mg/dL; (c) an increase in gamma globulin (IgG), usually with oligoclonal banding; and (d) positive serologic tests. The glucose content is usually normal. In congenital (but not adult) neurosyphilis, the earliest changes in the CSF, consisting of pleocytosis and an elevation of protein, may occur in the first few weeks of the infection, before the serologic tests become positive. Later, the CSF changes may vary. With either spontaneous or therapeutic remission of the disease, the cells disappear first; next the total protein returns to normal; and then the gamma globulin concentration is reduced. The positive serologic tests are the last to revert to normal. Frequently the CSF serology remains positive, despite repeated courses of therapy and the subsidence of all signs of inflammatory activity. When this occurs, it may be safely concluded that the syphilitic inflammation in the nervous system is burned out and that further progression of the disease probably will not occur. If treatment restores the CSF to normal, particularly the cell count and protein, arrest of the clinical symptoms almost always occurs. A return of cells and elevation of protein precedes or accompanies clinical relapse.

Serologic Diagnosis of Syphilis  This depends on the demonstration of one of two types of antibodies—nonspecific or nontreponemal (reagin) antibodies and specific treponemal antibodies. The common tests for reagin are the Kolmer, which uses a complement fixation technique, and the Venereal Disease Research Laboratory (VDRL) slide test, which uses a flocculation technique. These reagin tests, if positive in the CSF, are diagnostic of neurosyphilis. Serum reactivity alone demonstrates exposure to the organism in the past but does not imply the presence of neurosyphilis. However, serum reagin tests are negative in a significant proportion of patients with late syphilis and in those with neurosyphilis in particular (seronegative syphilis). In such patients (and in patients with suspected false-positive reagin tests), it is essential to employ tests for antibodies that are directed specifically against treponemal antigens. The latter are positive in the serum of practically every instance of neurosyphilis. The fluorescent treponemal antibody absorption (FTA-ABS) test is the one in common use and is more than adequate for the majority of clinical situations. The T. pallidum immobilization (TPI) test is the most reliable, but it is expensive, difficult to perform, and available in only a few laboratories.
Principal Types of Neurosyphilis

Asymptomatic Neurosyphilis In this condition, there are no symptoms or physical signs except, in rare cases, abnormal pupils which are light-unreactive but accommodate Argyll-Robertson pupils (see page 242). The diagnosis is based entirely on the CSF findings, which vary, as mentioned above.

Meningeal Syphilis Symptoms of meningeal involvement may occur at any time after inoculation but most often do so within the first 2 years. The most common symptoms are headache, stiff neck, cranial nerve palsies, convulsions, and mental confusion. Occasionally headache, papilledema, nausea, and vomiting—due to the presence of increased intracranial pressure—are added to the clinical picture. The patient is afebrile, unlike the case in tuberculous meningitis. The CSF is always abnormal, more so than in asymptomatic syphilitic meningitis. Obviously the meningitis is more intense in the symptomatic type and may be associated with hydrocephalus. With adequate treatment, the prognosis is good. The symptoms usually disappear within days to weeks, but if the CSF remains abnormal, it is likely that some other form of neurosyphilis will subsequently develop if treatment is not continued.

Meningovascular Syphilis This form of neurosyphilis should always be considered when a young person has one or several cerebrovascular accidents, i.e., the sudden development of hemiplegia, aphasia, sensory loss, visual disturbance, or mental confusion. As indicated earlier, this clinical syndrome is now probably the most common form of neurosyphilis. Whereas in the past strokes accounted for only 10 percent of neurosyphilitic syndromes, their frequency is now estimated to be 35 percent. The most common time of occurrence of meningovascular syphilis is 6 to 7 years after the original infection, but it may be as early as 9 months or as late as 10 to 12 years.

The CSF almost always shows some abnormality, usually an increase in cells, protein content, and gamma globulin as well as a positive serologic test. However, most patients in middle or late life with stroke and only a positive serologic test will be found at autopsy to have nonsyphilitic atherothrombotic or embolic infarction rather than meningovascular syphilis. The changes in the latter disorder consist not only of meningeal infiltrates but also of inflammation and fibrosis of small arteries (Heubner arteritis), which lead to narrowing and finally occlusion. Most of the infarctions occur in the distal territories of medium- and small-caliber lenticulostriate branches that arise from the stems of the middle and anterior cerebral arteries. Most characteristic perhaps is an internal capsular lesion, extending to the adjacent basal ganglia. The presence of multiple small but not contiguous lesions adjacent to the lateral ventricles is another common pattern. Small, asymptomatic lesions are often seen in the caudate and lenticular nuclei. Several of our patients had transient prodromal neurologic symptoms.

The neurologic signs that remain after 6 months will usually be permanent, but adequate treatment will prevent further vascular episodes. If repeated cerebrovascular accidents occur despite adequate therapy, one must always consider the possibility of nonsyphilitic vascular disease of the brain.

Paretic Neurosyphilis (General Paresis, Dementia Paralytica, Syphilitic Meningoencephalitis) The general setting of this form of cerebral syphilis is a long-standing meningitis; as remarked above, some 15 to 20 years usually separate the onset of general paresis from the original infection.

The history of the disease is entwined with some of the major historical events in neuropsychiatry. Haslam in 1798 and Esquirol at about the same time first delineated the clinical state. Bayle in 1822 commented on the arachnoiditis and meningitis, and Calmeil, on the encephalitic lesion. Nissl and Alzheimer added details to the pathologic descriptions. The syphilitic nature of the disease was suspected by Lasegue and others long before Schaudinn’s discovery of the spirochete; it was finally confirmed by Noguchi in 1913. Kraepelin’s monograph General Paresis (1913) is one of the classic reviews (see Merritt, Adams, and Solomon for these and other historical references).

Once a major cause of insanity, accounting for some 4 to 10 percent of admissions to asylums (hence the term “general paresis of the insane,” or GPI), general paresis is now a rarity. Since syphilis is acquired mainly in late adolescence and early adult life, the middle years (35 to 50) are the usual time of onset of the paretic symptoms. Possibly the shortened life span of patients with AIDS has limited the emergence of general paresis, or the immunodeficiency has altered the biologic reaction to the organism. Congenital syphilitic paresis blights early mental development and results in late childhood and adolescent regression in both normal and mentally retarded children.

The clinical picture in its fully developed form includes dementia, dysarthria, myoclonic jerks, action tremor, seizures, hyperreflexia, Babinski signs, and Argyll-Robertson pupils (page 242). However, more importance attaches to diagnosis at an earlier stage, when few of these manifestations are conspicuous. The insidious onset of memory defect, impairment of reasoning, and reduction in critical faculties—along with minor oddities of deportment and conduct, irritability, and lack of interest in personal appearance—are not too different from the general syndrome of dementia outlined in Chap. 21. One can appreciate how elusive the disease may be at any one point in its early evolution. Indeed, with the currently low index of suspicion of the disease, diagnosis at this preparalytic stage is more often accidental than deliberate.

Although classic writings have stressed the development of delusional systems, most dramatically in the direction of megalomania, such symptoms are exceptional in the early or preparalytic phase. More usual has been a simple dementia with weakening of intellectual capacities, forgetfulness, disorders of speaking and writing, and vague concerns about health. In a few patients the first hint of a syphilitic encephalitis, as mentioned earlier, may be facial quivering; tremulousness of the hands; indistinct, hurried speech; myoclonus; and seizures—reminiscent of delirium or acute viral encephalitis. As the deterioration continues into the paralytic stage, intellectual function progressively declines, and aphasias, agnosias, and apraxias intrude themselves.

Physical dissolution progresses concomitantly—impaired station and gait, debility, unsteadiness, dysarthria, and tremor of the tongue and hands. All these disabilities lead eventually to a bedridden state; hence the term paretic. Other symptoms are hemiplegia, hemianopia, aphasia, cranial nerve palsies, and seizures with prominent focal signs of unilateral frontal or temporal lobe disease—a syndrome known pathologically as Lissauer’s cerebral sclerosis. Normal-pressure hydrocephalus may be the basis of some of the cerebral symptoms. Agitated, delirious, depressive, and schizoid psychoses are special psychiatric syndromes that can be differentiated from general paresis by the lack of mental decline, neurologic signs, and CSF findings.
We have elaborated the neuropsychiatric features of this disease, even though rare nowadays, because they are manifest almost uniquely as a chronic frontotemporoparietal meningoencephalitis and create a picture unlike that of most degenerative diseases discussed in Chap. 39—with the possible exception of the newly popularized and imprecise category of “frontotemporal dementia.” Also, it is well to remember that many of our ideas about the brain and the mind were shaped historically by this disease.

The blood serology is positive in nearly all cases. The CSF is invariably abnormal, usually with 10 to 200 lymphocytes, plasma cells, and other mononuclear cells per cubic millimeter; a total protein of 40 to 200 mg/dL; an elevated gamma globulin; and strongly positive serologic tests. The elevated gamma globulin in the CSF is produced intrathecal and has been shown to be adsorbed to *T. pallidum* (Vartdal et al). Hence the gamma globulin (oligoclonal IgG) represents a specific antibody response to this organism.

The pathologic changes consist of meningeal thickening, brain atrophy, ventricular enlargement, and granular ependymitis. Microscopically, the perivascular spaces are filled with lymphocytes, plasma cells, and mononuclear cells; nerve cells have disappeared; there are numerous rod-shaped microgliocytes and plump astrocytes in parts of the cortex devastated by neuronal loss; iron is deposited in mononuclear cells; and, with special stains, spirochetes are visible in the cortex. The changes are most pronounced in the frontal and temporal lobes. The ependymal surfaces of the ventricles are studded with granular elevations protruding between ependymal cells (granular ependymitis). Meningeal fibrosis with obstructive hydrocephalus is present in many cases.

The prognosis in early treated cases has in the past been fairly good; 35 to 40 percent of patients made some occupational readjustment; in another 40 to 50 percent, the disease was arrested but left the patient dependent. Without treatment there is progressive mental decline, and death occurs within 3 to 4 years.

**Tabetic Neurosyphilis (Tabes Dorsalis)** This type of neurosyphilis, described by Duchenne in his classic monograph *L’ataxie locomotrice progressive* (1858), usually develops 15 to 20 years after the onset of the infection. The major symptoms are lightning pains, ataxia, and urinary incontinence; the chief signs are absent tendon reflexes at knee and ankle, impaired vibratory and position sense in feet and legs, and a Romberg sign. The ataxia is due purely to the sensory defect. Muscular power, by contrast, is fully retained in most cases. The pupils are abnormal in over 90 percent of cases, usually Argyll-Robertson in type (see page 242), and the majority of patients show ptosis or some degree of ophthalmoplegia. Optic atrophy is frequent. The lancinating or lightning pains (present in over 90 percent of cases) are, as their name implies, sharp, stabbing, and brief, like a flash of lightning. They are more frequent in the legs than elsewhere but roam over the body from face to feet, sometimes playing persistently on one spot “like the repeated twanging of a fiddle string,” as Wilson remarked. They may come in bouts lasting several hours or days. “Pins and needles” feelings, coldness, numbness, tingling, and other paresthesias are also present and are associated invariably with impairment of tactile, pain, and thermal sensation. The bladder is insensitive and hypotonic, resulting in unpredictable overflow incontinence. Constipation and megacolon as well as impotence are other expressions of dysfunction of the sacral roots and ganglia.

In the established phase of the disease, now seldom seen, ataxia is the most prominent feature. The patient totters and staggers while standing and walking. In mild form it is best seen as the patient walks between obstacles or along a straight line, turns suddenly, or halts. To correct the instability, the patient places his feet and legs wide apart, flexes his body slightly, and repeatedly contracts the extensor muscles of his feet as he sways (*la danse des tendons*). In moving forward, the patient flings his stiffened leg abruptly, and the foot strikes the floor with a resounding thump in a manner quite unlike that seen in the ataxia of cerebellar disease. The patient clatters along in this way with eyes glued to the floor. If his vision is blocked, he is rendered helpless. When the ataxia is severe, walking becomes impossible despite relatively normal strength of the leg muscles. Trophic lesions, perforating ulcers of the feet, and Charcot joints are characteristic complications of the tabetic state.

The deformity of deafferented Charcot joints occurs in less than 10 percent of tabetics (the most common cause nowadays is diabetic neuropathy). Most often the hips, knees, and ankles are affected but occasionally also the lumbar spine or upper limbs. The process generally begins as an osteoarthrosis, which, with repeated injury to the insensitive joint, progresses to destruction of the articular surfaces. Osseous architecture disintegrates, with fractures, dislocations, and subluxations, only some of which occasion discomfort. The arthropathy has been observed to occur as frequently in the burned-out as in the active phase of tabes; hence it is only indirectly related to the syphilitic process. Although the basic abnormality appears to be repeated injury to an anesthetic joint, the process need not be painless. Presumably a deep and incomplete hypesthesia and loss of autonomic function are enough to interfere with protective mechanisms. Sherrington reproduced the joint change in animals deprived of pain sensation.

Visceral crises represent another interesting manifestation of this disease, now rarely seen. The gastric ones are the best known. The patient is seized abruptly with epigastric pain that spreads around the body or up over the chest. There may be a sense of thoracic constriction as well as nausea and vomiting—the latter repeated until nothing but blood-tinged mucus and bile are raised. The symptoms may last for several days; a barium swallow sometimes demonstrates pylorospasm. The attack subsides as quickly as it came, leaving the patient exhausted, with a soreness of the epigastric skin. Intestinal crises with colic and diarrhea, pharyngeal and laryngeal crises with gulping movements and dyspnemic attacks, rectal crises with painful tenesmus, and genitourinary crises with strangury and dysuria are all less frequent but well-documented types.

In most cases now being seen, the CSF is normal when the patient is first examined (so-called burned-out tabes). In the remainder it is abnormal, but less often than in general paresis.

Pathologic study reveals a striking thinness and grayness of the posterior roots, principally lumbosacral, and a thinness of the spinal cord due mainly to the degeneration of the posterior columns. Only a slight outfall of neurons is observed in the dorsal root ganglia; the peripheral nerves are therefore essentially normal. For many years there was an argument as to whether the spirochete first attacked the posterior columns of the spinal cord, the posterior root as it pierced the pia, the more distal part of the radicular nerve where it acquires its arachnoid and dural sheaths, or the dorsal root ganglion cell. The observations of our colleagues of rare active cases have shown the inflammation to be all along the posterior root; the slight dorsal ganglion cell loss and posterior column degeneration were found to be secondary.

The hypotonia, areflexia, and ataxia relate to destruction of
proprioceptive fibers in the sensory roots. The hypotonia and insensitivity of the bladder are due to deafferentiation at the S2 and S3 levels; the same is true of the impotence and obstipation. Lightening pains and visceral crises cannot be fully explained but are probably attributable to incomplete posterior root lesions at different levels. Analgesia and joint insensitivity relate to the partial loss of A and C fibers in the roots.

If there is no pleocytosis, the CSF protein content is normal, and there is no evidence of cardiovascular or other types of syphilis, no further antisyphilitic treatment is necessary. If the CSF is positive, the patient should be treated with penicillin, as described below. Residual symptoms in the form of lightning pains, gastric crises, Charcot joints, or urinary incontinence frequently continue long after all signs of active neurosyphilitic infection have disappeared. These should be treated symptomatically rather than by antisyphilitic drugs.

**Syphilitic Optic Atrophy**
This takes the form of progressive blindness beginning in one eye and then involving the other. The usual finding is a constriction of the visual fields, but scotomata may occur in rare cases. The optic discs are gray-white. Other forms of neurosyphilis, particularly tabes dorsalis, not infrequently co-exist. The CSF is almost invariably abnormal, though the degree of abnormality may be slight in some cases. The prognosis is poor if vision in both eyes is greatly reduced. If only one eye is badly affected, sight in the other eye can usually be saved. In exceptional cases, visual impairment may progress, even after the CSF becomes negative. The pathologic changes consist of a perioptic meningitis, with subpial gliosis and fibrosis replacing degenerated optic nerve fibers. Exceptionally there are vascular lesions with infarction of central parts of the nerve.

**Spinal Syphilis**
There are several types of spinal syphilis other than tabes. Two of them, *syphilitic meningomyelitis* (sometimes called Erb’s paraplegia because of the predominance of bilateral corticospinal tract signs) and *spinal meningovascular syphilis*, are observed from time to time, though less often than tabes. Spinal meningovascular syphilis may occasionally take the form of an anterior spinal artery syndrome. In meningomyelitis, there occurs a subpial loss of myelinated fibers and gliosis as a direct result of the chronic fibrosing meningitis. Gumma of the spinal meninges and cord seldom is found. It was not present in a single case in Merritt and Adams’ study of spinal syphilis. Progressive muscular atrophy (syphilitic amyotrophy) is a very rare disease of questionable syphilitic etiology; most cases are degenerative (see Chap. 39). Also rare is syphilitic hypertrophic pachymeningitis or arachnoiditis, which allegedly gives rise to radicular pain, amyotrophy of the hands, and signs of long tract involvement in the legs (*syphilitic amyotrophy with spastic-ataxic paraparesis*). In all these syndromes there is an abnormal CSF unless, of course, the neurosyphilitic infection is burned out. (See Chap. 44, on spinal cord diseases.)

The prognosis in spinal neurosyphilis is uncertain. There is improvement or at least an arrest of the disease process in most instances, though a few patients may progress slightly after treatment is begun. A steady advance of the disease in the face of a negative CSF usually means that there has been a secondary constrictive myelopathy or that the original diagnosis was incorrect and the patient suffers from some other disease, e.g., a spinal form of multiple sclerosis as a degenerative disease.

**Syphilitic Nerve Deafness**
This may occur in either early or late syphilitic meningitis and may be combined with other syphilitic syndromes. We and our colleagues have had little clinical experience with this disorder and have no pathologic material.

**Treatment of Neurosyphilis**
The treatment of these tertiary forms of neurosyphilis consists of the administration of penicillin G, given intravenously in a dosage of 18 to 24 million units daily (3 to 4 million units every 4 h) for 14 days. Erythromycin and tetracycline, in doses of 0.5 g every 6 h for 20 to 30 days, are suitable substitutes in patients who are sensitive to penicillin. The so-called Jarisch-Herxheimer reaction, which occurs after the first dose of penicillin and is a matter of concern in the treatment of primary syphilis, is of little consequence in neurosyphilis; it usually consists of no more than a mild temperature elevation and leukocytosis.

The effects of treatment on certain symptoms of neurosyphilis, especially of tabetic neurosyphilis, are unpredictable and often little influenced by treatment with penicillin; they require other measures. Lightening pains may respond to gabapentin or carbamazepine. Analgesics may be helpful, but opiates should generally be avoided. Neuropathic (Charcot) joints require bracing or fusion. Atropine and phenothiazine derivatives are said to be useful in the treatment of visceral crises.

In all forms of neurosyphilis, the patient should be re-examined every 3 to 6 months and the CSF should be retested after a 6-month interval. If after 6 months the patient is free of symptoms and the CSF abnormalities have been reversed (disappearance of cells as well as reduction in protein, gamma globulin, and serology titers), no further treatment is indicated. Follow-up should include clinical examinations at 9 and 12 months and another lumbar puncture as part of the latter examination. Satisfactory progress is judged by absence of symptoms and further improvement in the CSF. These procedures should be repeated every 6 months until the CSF becomes completely negative. In the opinion of most experts, a persistent weakly positive serologic (VDRL) test after the cells and protein levels have returned to normal does not constitute an indication for additional treatment. Such a CSF formula assures that the disease is quiescent or arrested. Others are not convinced of the reliability of this concept and prefer to give more penicillin. If at the end of 6 months there are still an increased number of cells and an elevated protein in the fluid, another full course of penicillin should be given. Clinical relapse is almost invariably attended by recurrence of cells and increase in protein levels. Rapid clinical progression in the face of a negative CSF suggests the presence of a nonsyphilitic disease of the brain or cord. A proven maxim for treatment was that a syphilitic patient who has neither abnormal CSF nor aortitis needs no therapy. (In the days of arsenical treatment, the therapy put patients at greater risk than did the disease.) Finally, it may be said that even with the mild resurgence of the disease due to AIDS, the neurologist finds the various forms of neurosyphilis of more theoretical than practical importance. But no other disease has portrayed more vividly the effects of a chronic, continuously active cerebrospinal meningitis on the entire neuraxis.

**Lyme Disease (Erythema Chronicum Migrans; The Borrelioses)**

Until comparatively recent times, the nonvenereal treponematoses were of little interest to neurologists of the western world. Yaws, pinta, and endemic syphilis rarely if ever affected the nervous system. Leptospirosis was essentially an acute liver disease, with only one variant causing a nonicteric lymphocytic meningitis; tick-
louse-borne relapsing fevers were medical curiosities that did not involve neurologists. However, in the late 1970s, a multisystem disease with prominent neurologic features cropped up in the eastern United States. It was named after the town of Lyme, Connecticut, where a cluster of cases was first recognized in 1975. In 1982, Burgdorfer and colleagues identified the causative spirochetal agent, Borrelia burgdorferi. An early skin manifestation of the disease had previously been described in western Europe and referred to as erythema chronicum migrans. Later manifestations of the disease—taking the form of acute radicular pain followed by chronic lymphocytic meningitis and frequently accompanied by peripheral and cranial neuropathies—had long been known in Europe as the Bannwarth or Garin-Bujadoux syndrome. The identity of these diseases has been established, as well as their close relationship to relapsing fever—a disease that is also caused by spirochetes of the genus Borrelia and transmitted by ticks. The entire group is now classed as the borrelioses.

In humans, all these spirochetoses induce a subacute or chronic illness that evolves in ill-defined stages, with early spirochetemia, vascular damage in many organs, and a high level of neurotropism. As in syphilis, the nervous system is invaded early in the form of an asymptomatic meningitis. Later, neurologic abnormalities appear, but only in a proportion of such cases. The early neurologic complications are mainly derivations of meningitis. In this disease, unlike syphilis, peripheral and cranial nerves may be implicated (see further on and Chap. 46). Immune factors may be important in the later phases of the latent periods and in the development of the neurologic syndromes.

Lyme disease is less acute than leptosprirosis (Weil disease) and less chronic than syphilis. It successively involves the skin, nervous system, heart, and articular structures over a period of a year and then burns out. The infective organism, as stated above, is the spirochete B. burgdorferi, and the vector in the United States is the common ixodid tick. The precise roles of the infecting spirochete, the antibodies it induces, and other features of the human host response in the production of clinical symptoms and signs are not fully understood, but the development of an animal model by Pachner and colleagues suggests that there is a chronic form of Borrelia infection in the CNS.

Lyme borreliosis has a worldwide distribution, but the typical neurologic manifestations differ slightly in Europe and America, as emphasized in the review by Garcia-Monico and Benach. In the United States, where approximately 13,000 cases are reported annually, the disease is found mainly in the Northeast and the North Central states. Most infections are acquired from May to July. In 60 to 80 percent of cases, a skin lesion (erythema chronicum migrans) at the site of a tick bite is the initial manifestation, occurring within 30 days of exposure. It is a solitary, enlarging, ring-like erythematous lesion that may be surrounded by annular satellite lesions. Usually fatigue and influenza-like symptoms (myalgia, arthralgia, and headache) are associated, and these seem to be more prominent in the North American than the European form of the illness—possibly attributable to a more virulent species of spirochete (Nadelman and Wormser). Weeks to months later, neurologic or cardiac symptoms appear in 15 and 8 percent of the cases, respectively. Still later, if the patient remains untreated, arthritis or, more precisely, synovitis develops in about 60 percent of the cases. Death from this disease does not occur; therefore little is known of the pathology. A long period of disability is to be expected if the disease is not recognized and treated. Diagnosis is not difficult during the summer season in regions where the disease is endemic and when all the clinical manifestations are present. But in some cases, a skin lesion is not observed or may have been forgotten, or there may have been only a few or no secondary lesions and the patient is first seen in the neurologic phase of the illness. Then clinical diagnosis may be difficult.

**Neurologic Manifestations**

The usual pattern of neurologic involvement is one of an aseptic meningitis or a fluctuating meningoencephalitis with cranial or peripheral neuritis, lasting for months (Reik). By the time the neurologic disturbances appear, the systemic symptoms and skin lesions may have long since receded. An infrequent cardiac disorder, which may accompany or occur independently of the neurologic changes, takes the form of myocarditis, a pericarditis, or an atrioventricular block.

The initial nervous system symptoms are rather nonspecific. They consist of headache, mild stiff neck, nausea and vomiting, malaise, and chronic fatigue, fluctuating over a period of weeks to months. These symptoms relate to the meningitis. There is a CSF lymphocytosis with cell counts from 50 to 3000/mL and protein levels from 75 to 400 mg/dL, but both values are typically in the lower part of the range. Polymorphonuclear cells may be prominent in the early part of the illness. Usually the glucose content is normal. Somnolence, irritability, faulty memory, depressed mood, and behavioral changes have been interpreted as marks of encephalitis but are difficult to separate from the effects of meningitis. Seizures, choreic movements, cerebellar ataxia, and dementia have been reported but are infrequent. A myelitic syndrome, causing quadriplegia, is also documented.

In about half the cases, cranial neuropathies become manifest within weeks of onset of the illness. The most frequent is a unilateral or bilateral facial palsy, but involvement of other cranial nerves, including the optic nerve, has been observed, usually in association with meningitis. One-third to one-half of the patients with meningitis have multiple radicular or peripheral nerve lesions in various combinations. These are described in Chap. 46. In addition to facial palsies, a severe and painful meningoarculitits of the cauda equina (Bannwarth syndrome) is particularly characteristic and seems to be more common in Europe than in the United States (there are other causes of this syndrome, including herpesvirus and cytomegalovirus). There is also an infrequent occurrence of Guillain-Barré syndrome following Lyme infection, but there is no reason to believe that the illness then differs from other cases of the acute inflammatory demyelinating polyneuropathy that follows numerous other infections.

Because of the paucity of autopsy material, knowledge of the nature of Lyme encephalitis is still imprecise. Such pathologic material as is available has shown a perivascular lymphocytic inflammatory process of the leptomeninges and the presence of subcortical and periventricular demyelinating lesions, like those of multiple sclerosis (Fig. 32-6). Oski and colleagues have recovered B. burgdorferi DNA from the involved areas, suggesting that the encephalitis is due to direct invasion by the spirochete.

A problematic aspect of Lyme disease relates to the development in some patients of a mild chronic encephalopathy, coupled with extreme fatigue. That such a disorder may occur after a well-documented attack of Lyme disease is undoubted. However, in the absence of a history of the characteristic rash, arthritis, or well-documented aseptic meningitis, the attribution to Lyme disease of fatigue alone or various other vague mental symptoms, such as difficulty in concentration, is almost always erroneous, even if there is serologic evidence of prior exposure to the spirochete. It would
be an understatement to indicate that a number of patients are persuaded that various symptoms are the result of Lyme infection and seek and receive unnecessary treatment.

Serologic tests are of great value but again must be interpreted with caution if there has not been an inciting clinical syndrome of erythema chronicum migrans or arthritis or a well-documented tick bite. The most valuable initial screening is performed by the enzyme-linked immunosorbent assay (ELISA); if both acute and convalescent sera are tested, about 90 percent of patients have a positive IgM response. After the first few weeks, most patients have elevated IgG antibody responses to the spirochete (Berardi et al); a positive test of this nature may simply reflect prior exposure. False-positive tests do occur in some of the conditions that react to syphilitic reagin B. burgdorferi—specific antibodies can also be demonstrated in the CSF. Positive ELISA testing should be pursued further with Western blot or immunoblot analysis or other more specific serologies in clinically uncertain cases. Although these latter tests are difficult to carry out and have not been standardized, the presence of both IgG and IgM antibodies is strongly supportive of a recent infection, whereas the IgG is useful in later cases. These complex laboratory issues are discussed and put in perspective by Golightly. In about 30 percent of cases, the organism can be detected in the spinal fluid using PCR techniques. In the chronic phase of the disease, CT and MRI in cases of encephalopathy may display multifocal and periventricular cerebral lesions (Fig. 32-6), but these are by no means indicative alone of Lyme disease, as they also appear in numerous other conditions.

**Treatment**
The recommended treatment in the first stage of the disease is oral tetracycline (250 mg qid) or doxycycline (100 mg bid). CNS cardiac and arthritic disease can thereby be prevented. Once the meninges and nervous system are implicated, high-dose penicillin, 20 million units daily for 10 to 14 days, or, probably more effective, ceftriaxone, 2 g daily, must be given intravenously for a similar period. Tetracycline, 500 mg four times a day for 30 days, is recommended by Reik for patients who are allergic to these intravenous drugs. For late abnormalities, no treatment has proved to be effective. However, most of the symptoms tend to regress regardless of the type of treatment given.

**Leptospirosis**
This systemic spirochetal infection, caused by *Leptospira interrogans*, is characterized primarily by hepatitis but may include an aseptic meningitis during the second part of a biphasic illness. Initially there is high fever, tender muscles, chest and abdominal pain, and cough. An extreme form (Weil disease) comprises hepatic and renal failure. Prominent conjunctival suffusion and photophobia are typical of leptospirosis and should draw attention to the diagnosis. The CSF during the meningitic stage contains approximately 100 lymphocytes per milliliter, but cell counts in excess of 10,000 have been reported and the protein concentration may reach high levels. Subarachnoid and intracerebral bleeding, probably from inflamed blood vessels, are known to occur. The diagnosis is made by serologic methods (complement fixation screening followed by specific agglutination tests). Antibiotic treatment seems to be effective only if implemented during the initial febrile phase. The meningitis is usually self-limited.

**Fungal Infections of the Nervous System**

Described in the following pages are a number of infectious diseases, much less common than bacterial ones, in which a systemic infection may secondarily involve the CNS. For the neurologist, the diagnosis rests on two lines of clinical information—one, evidence of infection in the skin, lungs, or other organs, and two, the appearance of a subacute meningeal or multifocal encephalitic disorder. Once demonstrated, the nature of the neurologic disorder is determined by identifying the infective agent in the CSF, by appropriate immunologic tests, and by the biopsy of nonneurologic tissue or brain.

Although a large number of fungal diseases may involve the nervous system, only a few do so with any regularity. Of 57 cases assembled by Walsh and coworkers, there were 27 of candidiasis, 16 of aspergillosis, and 14 of cryptococcosis. Among the opportunistic mycoses (see below), 90 to 95 percent are accounted for by species of Aspergillus and Candida. Mucormycosis and coccidioidomycosis are far less frequent, and blastomycosis and actinomycosis (*Nocardia*) occur only in isolated instances. However, all of these infections, particularly cryptococcal meningitis, are being seen more frequently, mainly in association with AIDS.

**General Features**
Fungal infections of the CNS may arise without obvious predisposing cause, but frequently they complicate some other disease process such as AIDS, organ transplantation, severe burns, leukemia, lymphoma or other malignancy, diabetes, collagen vascular disease, or prolonged corticosteroid therapy. The factors operative in these clinical situations are not fully understood, but interference with the body’s normal flora and impaired T-cell and humoral responses are the most obvious ones. Thus fungal infections tend to occur in patients with leukopenia, inadequate T-lymphocyte function, or insufficient antibodies. Infections related to impairment of the body’s protective mechanisms are referred to as opportunistic and include not only fungal infections but also those due to certain bacteria (*Pseudomonas* and other gram-negative organisms,
L. monocytogenes, protozoa (Toxoplasma), and viruses (cytomegaloivirus, herpes simplex, and varicella zoster). It follows that these types of infection should always be considered and sought in the aforementioned clinical situations.

Fungal meningitis develops insidiously, as a rule, over a period of several days or weeks, similar to tuberculous meningitis; the symptoms and signs are also much the same as with tuberculous infection. Involvement of several cranial nerves, arteritis with thrombosis and infarction of brain, multiple cortical and subcortical microabscesses, and hydrocephalus frequently complicate the course of fungal meningitis, just as they do in all chronic meningitides. Often the patient is afebrile or has only intermittent fever.

The spinal fluid changes in fungal meningitis are also like those of tuberculous meningitis. Pressure is elevated to a varying extent, pleocytosis is moderate, and lymphocytes predominate. Exceptionally, in acute cases, a pleocytosis above 1000 per cubic millimeter and a predominant polymorphonuclear response are observed. On the other hand, in patients with AIDS or with leukopenia for other reasons, the pleocytosis may be minimal or even absent. Glucose is subnormal and protein is elevated, sometimes to very high levels.

The specific diagnosis can best be made from smears of the CSF sediment and from cultures and also by demonstrating antigens of the organism by immunodiffusion, latex particle agglutination, or comparable antigen recognition tests. The CSF examination should also include a search for tubercle bacilli and abnormal white cells because of the not infrequent concurrence of fungal infection and tuberculosis, leukemia, or lymphoma.

Some of the special features of the more common fungal infections are indicated below.

**Cryptococcosis (Torulosis, European Blastomycosis)** Cryptococcosis (formerly called torulosis) is one of the more frequent fungal infections of the CNS. The cryptococcus is a common soil fungus found in the roosting sites of birds, especially pigeons. Usually the respiratory tract is the portal of entry, less often the skin and mucous membranes. The pathologic changes are those of a granulomatous meningitis; in addition, there may be small granulomas and cysts within the cerebral cortex, and sometimes large granulomas and cystic nodules form deep in the brain (cryptococcomas). The cortical cysts contain a gelatinous material and large numbers of organisms; the solid granulomatous nodules are composed of fibroblasts, giant cells, aggregates of organisms, and areas of necrosis.

Cryptococcal meningitis has a number of distinctive clinical features. Most cases are acquired outside the hospital and evolve subacutely, like other fungal infections or tuberculosis. A few of our cases have had an explosive onset, rendering the patient quite ill in a day. In the majority of patients, the early complaints are headache, nausea, and vomiting; mental changes are present in about half. In other cases, however, headaches, fever, and stiff neck are lacking altogether, and the patient presents with symptoms of gradually increasing intracranial pressure due to hydrocephalus (papilledema is present in half such patients) or with a confusional state, dementia, cerebellar ataxia, or spastic paraparesis, usually without other focal neurologic deficit. Furthermore, large series of affected patients indicate that 20 to 40 percent of patients have no fever when first examined (the figure applies to patients without AIDS); we suspect that more frequent measurement of temperature would give a greater incidence of fever. Cranial nerve palsies are infrequent findings. Rarely, a granulomatous lesion forms in one part of the brain, and the only clue to the etiology of the cerebral mass is a lung lesion and an abnormality of the CSF. Meningovascular lesions, presenting as small deep strokes in an identical manner to meningoencephalitis, may be superimposed on the clinical picture. A pure motor hemiplegia, like that due to a hypertensive lacune, has been the most common type of stroke in our experience.

The course of the disease is quite variable. It may be fatal within a few weeks if untreated. More often, the course is steadily progressive over a period of several weeks or months; in a few patients, it may be remarkably indolent, lasting for years, during which there may be periods of clinical improvement and normalization of the CSF. Lymphoma, Hodgkin disease, leukemia, carcinoma, tuberculosis, and other debilitating diseases that alter the immune responses are predisposing factors in as many as half the patients. Patients with AIDS are particularly vulnerable to cryptococcal infection; estimates are that 5 to 10 percent of AIDS patients are subject to life-threatening meningoencephalitis with the organism.

The spinal fluid shows a variable lymphocytic pleocytosis, usually less than 50 cells per cubic millimeter, but it should be emphasized that there may be fewer than cells in a patient with AIDS (two-thirds have 5 or fewer cells per cubic millimeter). The initial CSF findings may display polymorphonuclear cells, but it rapidly changes to a lymphocytic predominance. The glucose is reduced in three-quarters of cases (again, it may be normal in AIDS patients) and the protein may reach high levels. Specific diagnosis depends upon finding Cryptococcus neoformans or its antigens in the CSF. These are spherical cells, 5 to 15 μm in diameter, which retain Gram’s stain and are surrounded by a thick, refractile capsule. Large volumes of CSF (20 to 40 mL) may be needed to find the organism in some cases, but in others they are prolific. India ink preparations are distinctive and diagnostic in experienced hands (debris and talc particles from the gloves used in lumbar puncture may be mistaken for the organism), but the rate of positive tests under the best circumstance is 75 percent. The carbon particles fail to penetrate the capsule, leaving a wide halo around the doubly refractile wall of the organism. The search for these organisms is particularly important in AIDS patients, in whom the CSF values for cells, glucose, and proteins may be entirely normal. A latex agglutination test for the cryptococcal polysaccharide antigen in the CSF is now widely available and gives rapid results. The latter test, if negative, excludes cryptococcal meningitis with about a 90 percent reliability in AIDS patients and slightly less in others (see Chuck and Sande). In most cases the organisms grow readily in Sabouraud glucose agar at room temperature and at 37°C, but these results may not appear for days. Newer enzyme-linked immunoadsorption tests are being evaluated.

The principal diseases to be considered in differential diagnosis are tuberculous meningitis (distinguished by fever, distinctive pulmonary lesions, low serum sodium due to inappropriate secretion of ADH, and organisms in CSF); granulomatous cerebral vasculitis (normal glucose values in CSF); multifocal leukencephalopathy (negative CSF); unidentified forms of viral meningoencephalitis (normal CSF glucose values); sarcoidosis; and lymphomatosis or carcinomatosis of meninges (neoplastic cells in CSF).

**Treatment** In patients without AIDS, this consists of intravenous administration of amphotericin B, given in a dose of 0.5 to 0.7 mg/kg/day. Intrathecal administration of the drug in addition to the intravenous route appears not to be essential. Administration of the
drug should be discontinued if the blood urea nitrogen reaches 40 mg/dL and resumed when it descends to normal levels. Renal tubular acidosis also frequently complicates amphotericin B therapy. The addition of flucytosine (150 mg/kg/day) to amphotericin B results in fewer failures or relapses, more rapid sterilization of the CSF, and less nephrotoxicity than the use of amphotericin B alone because it permits the reduction of the amphotericin dose to 0.3 to 0.5 mg/kg/day. Both medications are usually continued for at least 6 weeks—longer if CSF cultures remain positive. However, this regimen, which has a success rate of 75 to 85 percent in immunocompetent patients, has proven to be much less effective in patients with AIDS. Such patients are also extremely sensitive to flucytosine and about half of them are forced to discontinue this drug because of neutropenia. Fluconazole, an oral triazole antifungal agent given in a dosage up to 400 mg daily, or oral itraconazole (up to 200 mg per day) are alternatives to flucytosine in AIDS patients and are considerably more effective in preventing relapse if given indefinitely (Saag et al; Powderly et al). The optimum use of these drugs has not been settled, and some trials have yielded ambiguous results in both AIDS and other patients. A current perspective on treatment can be obtained in the reference of Tunkel and Scheld.

Mortality from cryptococcal meningocerephalitis, even in the absence of AIDS or other disease, is about 40 percent.

**Candidiasis (Moniliasis)** Candidiasis is probably the most frequent type of opportunistic fungus infection, but it is far less common than cryptococcosis. The most notable antecedents of Candida sepsis are severe burns and the use of total parenteral nutrition, especially in children. Urine, blood, skin, and particularly the heart (myocardium and valves) and lungs (alveolar proteinosis) are the usual sites of primary infection. No special features distinguish this fungal infection from others; meningitis, meningoencephalitis, and cerebral abscess, usually multiple and small, are the main modes of clinical presentation. Lipton and colleagues, who reviewed 2631 autopsy records at the Peter Bent Brigham Hospital (1973 to 1980), found evidence of Candida infection in 28 cases, in half of which the CNS was infected. These infections took the form of scattered intraparenchymal microabscesses, noncaseating granulomas, large abscesses, and meningitis and ependymitis (in that order of frequency). In most of these cases, the diagnosis had not been made during life, possibly because of the difficulty of obtaining the organism from the CSF. Generally the CSF contains several hundred (up to 2000) cells per cubic millimeter. Yeast can be seen on direct microscopy in half the cases. Even with treatment (intravenous amphotericin B), the prognosis is extremely grave.

**Aspergillosis** In most instances, this fungal infection has presented as a chronic sinusitis (particularly sphenoidal), with osteomyelitis at the base of the skull or as a complication of otitis and mastoiditis. Cranial nerves adjacent to the infected bone or sinus may be involved. We have also observed brain abscesses and cranial and spinal dural granulomas. In one of our patients, the Aspergillus organisms had formed a granulomatous mass that compressed the cervical spinal cord. Aspergillosis does not present as a meningitis but hyphal invasion of cerebral vessels may occur, with thrombosis, necrosis, and hemorrhage. In some cases the infection is acquired in the hospital, and in most it is preceded by a pulmonary infection that is unresponsive to antibiotics. Diagnosis can often be made by finding the organism in a biopsy specimen or culturing it directly from a lesion. Also, specific antibodies are detectable. Amphotericin B in combination with 5-fluorocytosine and imidazole drugs is the recommended treatment, but this regimen is not as effective for aspergillosis as it is for cryptococcal disease. The addition of itraconazole, 200 mg bid, in less immunocompromised patients is recommended. If amphotericin B is given after surgical removal of the infected material, some patients recover.

**Mucormycosis (Zygomycosis, Phycomycosis)** This is a malignant infection of cerebral vessels with one of the Mucorales. It occurs as a rare complication in patients with diabetic acidosis, in drug addicts, and in patients with leukemia and lymphoma, particularly those treated with corticosteroids and cytotoxic agents.

The cerebral infection begins in the nasal turbinates and paranasal sinuses and spreads from there along infected vessels to the retro-orbital tissues (where it results in proptosis, ophthalmoplegia, and edema of the lids and retina) and then to the adjacent brain, causing hemorrhagic infarction. Numerous hyphae are present within the thrombi and vessel wall, often invading the surrounding parenchyma. The cerebral form of mucormycosis is usually fatal in short order. Rapid correction of hyperglycemia and acidosis and treatment with amphotericin B have resulted in recovery in some patients.

**Coccidioidomycosis, Histoplasmosis, Blastomycosis, and Actinomycosis** *Coccidioidomycosis* is a common infection in the southwestern United States. It usually causes only a benign, influenza-like illness with pulmonary infiltrates that mimic those of nonbacterial pneumonia; but in a few individuals (0.05 to 0.2 percent), the disease takes a disseminated form, of which meningitis may be a part. The pathologic reactions in the meninges and CSF and the clinical features are very much like those of tuberculous meningitis. *Coccidioides immitis* is recovered with difficulty from the CSF but readily from the lungs, lymph nodes, and ulcerating skin lesions.

Treatment consists of the intravenous administration of amphotericin B coupled with implantation of an Ommaya reservoir into the lateral ventricle, permitting injection of the drug for a period of years. Instillation of the drug by repeated lumbar punctures is an alternative albeit cumbersome procedure. Even with the most assiduous programs of treatment, only about half the patients with meningeal infections survive.

A similar type of meningitis may occasionally complicate histoplasmosis, blastomycosis, and actinomycosis. These chronic meningitides possess no specific features except that actinomycosis, like some cases of tuberculosis and nocardiosis, may cause a persistent polymorphonuclear pleocytosis (see page 635). The CSF yields an organism in a minority of patients, so that diagnosis depends upon culture from extraneural sites, biopsy of brain abscesses if present, as well as knowledge of the epidemiology of these fungi. Patients with chronic meningitis in whom no cause can be discovered should also have their CSF tested for antibodies to *Sporothrix schenckii*, an uncommon fungus that is difficult to culture. Several even rarer fungi that must be considered in the diagnosis of chronic meningitides are discussed in the article by Swartz. Penicillin is the drug of choice in actinomycosis; amphotericin B and supplemental antifungal agents are used in the others. Intrathecal amphotericin is administered in patients who relapse.
INFECTIONS CAUSED BY RICKETTSIAS, PROTOZOA, AND WORMS

Rickettsial Diseases

Rickettsias are obligate intracellular parasites that appear microscopically as pleomorphic coccobacilli. The major ones are maintained in nature by a cycle involving an animal reservoir, an insect vector (lice, fleas, mites, and ticks), and humans. Epidemic typhus is an exception, involving only lice and human beings, and Q fever is probably contracted by inhalation. At the time of the First World War, the rickettsial diseases, typhus in particular, were remarkably prevalent and of the utmost gravity. In eastern Europe, between 1915 and 1922, there were an estimated 30 million cases of typhus with 3 million deaths. Now, the rickettsial diseases are of minor importance, the result of insect control by DDT and other chemicals and the therapeutic effectiveness of broad-spectrum antibiotics. In the United States these diseases are quite rare, but they assume importance, the result of insect control by DDT and other chemicals and the therapeutic effectiveness of broad-spectrum antibiotics. In the United States these diseases are quite rare, but they assume significance because, in some types, up to one-third of patients have neurologic manifestations. About 200 cases of Rocky Mountain spotted fever (the most common rickettsial disease) occur each year in the United States, with a mortality of 5 percent or less. Neurologic manifestations occur in a small portion, and neurologists may not encounter a single instance in a lifetime of practice. For this reason, the rickettsial diseases are simply tabulated here. (A comprehensive account may be found in Harrison's Principles of Internal Medicine.)

The following are the major rickettsial diseases:

1. **Epidemic typhus**, small pockets of which are present in many undeveloped parts of the world. It is transmitted from lice to humans and from person to person.
2. **Murine (endemic) typhus**, which is present in the same areas as Rocky Mountain spotted fever (see below). It is transmitted by rat fleas from rats to humans.
3. **Scrub typhus** or *tsutsugamushi* fever, which is confined to eastern and southeastern Asia. It is transmitted by mites from infected rodents or humans.
4. **Rocky Mountain spotted fever**, first described in Montana, is most common in Long Island, Tennessee, Virginia, North Carolina, and Maryland. It is transmitted by special varieties of ticks.
5. **Q fever**, which has a worldwide distribution (except for the Scandinavian countries and the tropics). It is transmitted in nature by ticks but also by inhalation of dust and handling of materials infected by the causative organism, *Coxiella burnetii*.

With the exception of Q fever, the clinical manifestations and pathologic effects of the rickettsial diseases are much the same, varying only in severity. Typhus may be taken as the prototype. The incubation period varies from 3 to 18 days. The onset is usually abrupt, with fever rising to extreme levels over several days; headache, often severe; and prostration. A macular rash, which resembles that of measles and involves the trunk and limbs, appears on the fourth or fifth febrile day. An important diagnostic sign in scrub typhus is the necrotic ulcer and eschar at the site of attachment of the infected mite. Delirium—followed by progressive stupor and coma, sustained fever, and occasionally focal neurologic signs and optic neuritis—characterizes the untreated cases. Stiffness of the neck is noted only rarely, and the CSF may be entirely normal or show only a modest lymphocytic pleocytosis.

In fatal cases, the rickettsial lesions are scattered diffusely throughout the brain, affecting gray and white matter alike. The changes consist of swelling and proliferation of endothelial cells of small vessels and a microglial reaction, with the formation of so-called typhus nodules.

**Q fever**, unlike the other rickettsioses, is not associated with an exanthem or agglutinins for the *Proteus* bacteria (Felix-Weil reaction). In the few cases with which we are familiar, the main symptoms were those of a low-grade meningitis. Rare instances of encephalitis, cerebellitis, and myelitis are also reported, possibly as postinfectious complications. There is usually a tracheobronchitis or atypical pneumonia (one in which no organism can be cultured from the sputum) and a severe prodromal headache. In these respects, the pulmonary and the neurologic illness resembles that of the other main cause of “atypical pneumonia,” *M. pneumoniae*. The Q fever agent (*Coxiella*) should be suspected if there are concomitant respiratory and meningoencephalitic illnesses and there has been exposure to parturient animals, to livestock (including abattoir workers), or to wild deer or rabbits. The diagnosis can be made by the finding of a severalfold increase in specific immunofixation antibodies. Patients who survive the illness usually recover completely; a few are left with residual neurologic signs.

**Treatment** This consists of the administration of chloramphenicol or tetracycline, which are highly effective in all rickettsial diseases. If these drugs are given early, coincident with the appearance of the rash, symptoms abate dramatically and little further therapy is required. Cases recognized late in the course of the disease require considerable supportive care, including the administration of corticosteroids, maintenance of blood volume to overcome the effects of the septic-toxic reaction, and hypoproteinemia.

Protozoal Diseases

**Toxoplasmosis** This disease is caused by *Toxoplasma gondii*, a tiny (2- to 5-μm) obligate intracellular parasite that is readily recognized in Wright- or Giemsa-stained preparations. It has assumed great importance in recent decades because of the frequency with which it involves the brain in patients with AIDS. Infection in humans is either congenital or acquired postnatally. Congenital infection is the result of parasitemia in the mother who happens to be pregnant at the time of her initial (asymptomatic) *Toxoplasma* infection. (Mothers can be assured, therefore, that there is no risk of producing a second infected infant.) Several modes of transmission of the late acquired form have been described—eating raw beef, handling uncooked mutton (in western Europe), and, most often, contact with cat feces, the cat being the natural host of *Toxoplasma*. Most infections in AIDS patients occur in the absence of an obvious source.

The congenital infection has attracted attention because of its severe destructive effects on the neonatal brain, as discussed in Chap. 38. Signs of active infection—fever, rash, seizures, hepatosplenomegaly—may be present at birth. More often, chorioretinitis, hydrocephalus or microcephaly, cerebral calcifications, and psychomotor retardation are the major manifestations. These may become evident soon after birth or only several weeks or months later. Most infants succumb; others survive with varying degrees of the aforementioned abnormalities.
Serologic surveys indicate that the acquired form of toxoplasmosis in adults is widespread and frequent (about 40 percent of American city dwellers have specific antibodies); however, cases of clinically evident active infection are rare. It is of interest that in 1975 the medical literature contained only 45 well-documented cases of acquired adult toxoplasmosis (Townsend et al); moreover, in half of them there was an underlying systemic disease (malignant neoplasms, renal transplants, collagen vascular disease) that had been treated intensively with immunosuppressive agents. Now, innumerable cases of acquired toxoplasmosis are being seen because it is the most common cause of focal cerebral lesions in patients with AIDS (see Chap. 33, page 646). Frequently, the symptoms and signs of infection with Toxoplasma are assigned to the primary disease with which toxoplasmosis is associated, and an opportunity for effective therapy is missed.

The clinical picture in patients without AIDS varies. There may be a fulminant, widely disseminated infection with a rickettsia-like rash, encephalitis, myocarditis, and polymyositis. Or the neurologic signs may consist only of myoclonus and asterixis, suggesting a metabolic encephalopathy. More often, there are signs of a meningoencephalitis, i.e., seizures, mental confusion, meningeal irritation, coma, and a lymphocytic pleocytosis and increased CSF protein. The brain in such cases shows foci of inflammatory necrosis (Fig. 32-7), with free and encysted T. gondii organisms scattered throughout the white and gray matter. Rarely, large areas of necrosis manifest themselves as one or more mass lesions. Or, a nodular lesion is detected on MR or CT imaging that is performed for other reasons.

Specific diagnosis depends on the finding of organisms in CSF sediment and occasionally in biopsy specimens of muscle or lymph node. A presumptive diagnosis can be made on the basis of a rising antibody titer or a positive IgM indirect fluorescent antibody or other serologic test. Patients with AIDS and those who are otherwise immunocompromised, however, usually do not display this response (those with lymphoma do have positive serologic tests). Excepting the AIDS cases, a clinical syndrome and radiologic features that are consistent with toxoplasmosis and a greatly elevated IgG titer are thought to be diagnostic. In the setting of AIDS, patients with multiple nodular or ring-enhancing brain lesions are treated initially with antibiotics for toxoplasmosis, and further evaluation (mainly for cerebral lymphoma) is undertaken only if there is no response, as discussed in Chap. 33.

Treatment All patients with a presumptive diagnosis should be treated with oral sulfadiazine (4 g initially, then 2 to 6 g daily) and pyrimethamine (100 to 200 mg initially, then 25 mg daily). Leucovorin, 2 to 10 mg daily, should be given to counteract the antifolate action of pyrimethamine. Treatment must be continued for at least 4 weeks. In patients with AIDS, treatment is continued until the CD4 count exceeds 200 to 250 for 6 months or more; otherwise treatment must be lifelong in order to prevent relapses.

Amebic Meningoencephalitis This disease is caused by free-living flagellate amebae, usually of the genus Naegleria and less frequently of the genus Hartmannella (Acanthamoeba and Balamuthia mandrillaris). They are acquired by swimming in ponds or lakes where the water is contaminated. One outbreak in Czechoslovakia followed swimming in a chlorinated indoor swimming pool. Most of the cases in the United States have occurred in the southeastern states. As of 1989, more than 140 cases of primary amebic meningoencephalitis due to Naegleria fowleri and more than 40 cases due to the less virulent Acanthamoeba had been reported (Ma et al).

The onset of the illness due to Naegleria is usually abrupt, with severe headache, fever, nausea and vomiting, and stiff neck. The course is inexorably progressive—with seizures, increasing stupor and coma, and focal neurologic signs—and the outcome is practically always fatal, usually within a week of onset. The reaction in the CSF is like that in acute bacterial meningitis: increased pressure, a large number of polymorphonuclear leukocytes (not eosinophils, as in the parasitic infestations discussed on page 628), and an increased protein and decreased glucose content. The diagnosis depends on eliciting a history of swimming in fresh warm water, particularly of swimming underwater for sustained periods, and on finding viable trophozoites in a wet preparation of unspun water, particularly of swimming underwater for sustained periods, and on finding viable trophozoites in a wet preparation of unspun water. Gram’s stain and ordinary cultures do not reveal the organism. Autopsy discloses a purulent meningitis and numerous quasigranulomatous microabscesses in the underlying cortex.

Subacute and chronic amebic meningoencephalitis is a rare disease in humans. Isolated instances, due to Hartmannella species, have been reported in debilitated and immunosuppressed patients (Gonzalez et al). Usually these patients will have amebic abscesses in the liver and sometimes in the lung and brain. The organism can be cultured from the CSF during periods of recurrent seizures and confusion. A fatal case of ours, in a leukopenic patient who had been receiving granulocyte-stimulating factor, ran a subacute course over 1 month with headache, mild fever, stupor, and unmeasurably low CSF glucose toward the end of life. Initially, there were scattered, round, enhancing lesions on the MRI that disappeared with corticosteroids, much like lymphoma; later, there were more irregular

Figure 32-7. Toxoplasmosis. MRI of the brain in the axial plane showing widespread high-signal lesions with prominent ring enhancement. The patient was a 28-year-old man with AIDS. Typically, there are fewer lesions than shown here.
confluent white matter lesions. A brain biopsy revealed amebae that could have been easily mistaken for macrophages or cellular debris; the organism proved to be *Balamuthia* (Katz et al.).

Treatment with the usual antiprotozoal agents is largely ineffective. Because of the in vitro sensitivity of *Naegleria* to amphotericin B, this drug should be used by the same schedule as for cryptococcal meningitis. With such a regimen in combination with rifampin, recovery is sometimes possible.

**Malaria** A number of other protozoal diseases are of great importance in tropical regions. One is cerebral malaria, which complicates about 2 percent of cases of *falciparum malaria*. This is a rapidly fatal disease characterized by headache, seizures, and coma, with diffuse cerebral edema and only very rarely by focal features such as hemiplegia, aphasia, hemianopia, or cerebellar ataxia. Cerebral capillaries and venules are packed with parasitized erythrocytes and the brain is dotted with small foci of necrosis surrounded by glia (Durck nodes). These findings have been the basis of several hypotheses (one of which attributes the cerebral symptoms to mechanical obstruction of the vessels), but none is entirely satisfactory. Also, it seems unlikely that a disorder of immune mechanisms is directly involved in the pathogenesis (see reviews by Newton et al and by Turner for a discussion of current hypotheses).

Usually the neurologic symptoms appear in the second or third week of the infection, but they may be the initial manifestation. Children in hyperendemic regions are the ones most susceptible to cerebral malaria. Among adults, only pregnant women and non-immune individuals who discontinue prophylactic medication are liable to CNS involvement (Toro and Roman). Useful laboratory findings are anemia and parasitized red blood cells. The CSF may be under increased pressure and sometimes contains a few white blood cells, and the glucose content is normal. With *Plasmodium vivax* infections, there may be drowsiness, confusion, and seizures without invasion of the brain by the parasite.

**Treatment** Quinine, chloroquine, and related drugs are curative if the cerebral symptoms are not pronounced, but once coma and convulsions supervene, 20 to 30 percent of patients do not survive. It has been stated that the administration of large doses of dexamethasone, given as soon as cerebral symptoms appear, may be lifesaving, but most studies including those of our colleagues have expressed the view that corticosteroids are ineffective. Exchange transfusion may confer a small benefit on survival in severe cases.

**Trypanosomiasis** This is a common disease in equatorial Africa and in Central and South America. The African type (“sleeping sickness”) is caused by *Trypanosoma brucei* and is transmitted by several species of the tsetse fly. There has been an alarming increase in this disease in sub-Saharan Africa during the last two decades. The infection begins with a chancre at the site of inoculation and localized lymphadenopathy. Posterior cervical adenopathy is highly characteristic of CNS infection (Winterbottom sign); another sign of neurologic interest is pronunced pain at sites of minor injury (called Kerandel hyperesthesia). Later, episodes of parasitemia occur, and at some time during this stage of dissemination, usually in the second year of the infection, the trypanosomes give rise to a diffuse meningoencephalitis. The latter expresses itself clinically as a chronic progressive neurologic syndrome consisting of a reversal or disruption of circadian sleep rhythm, vacant facial expression, and in some, paresis and ophthalmoplegia, dysarthria, and then muteness, seizures, progressive apathy, stupor, and coma.

The South American variety of trypanosomiasis (Chagas disease) is caused by *Trypanosoma cruzi* and is transmitted from infected animals to humans by the bite of reduvid bugs. The sequence of local lymphadenopathy, hematogenous dissemination, and chronic meningoencephalitis is like that of African trypanosomiasis. Serologic tests are available to confirm the diagnosis.

**Treatment** Treatment is with pentavalent arsenicals, mainly melarsoprol, which are more effective in the African than in the South American form of the disease. Anencephalopathy occurs in one-fifth of cases during the institution of treatment. Unusually high rates of relapse are being reported after treatment. A thorough review of the subject of trypanosomiasis is given by Barrett and colleagues. They also discuss the important topic of vector control.

**Diseases Caused by Nematodes** (Table 32-6)

Of these, trichinosis is of greatest importance to neurologists. Infections with other roundworms, such as *Angiostrongylus*, cause an eosinophilia-like meningitis, as discussed further on.

**Trichinosis** This disease is caused by the intestinal nematode *Trichinella spiralis*. Infection in humans results from the ingestion of uncooked or undercooked pork (occasionally bear meat) containing the encysted larvae of *T. spiralis*. The larvae are liberated from their cysts by the gastric juices and develop into adult male and female worms in the duodenum and jejunum. After fertilization, the female burrows into the intestinal mucosa, where she deposits several successive batches of larvae. These make their way—via the lymphatics, regional lymph nodes, thoracic duct, and bloodstream—into all parts of the body. The new larvae penetrate all tissues but survive only in muscle, where they become encysted and eventually calcify. Animals are infected in the same way as humans, and the cycle can be repeated only if a new host ingests the encysted larvae. Gould has written an authoritative review of this subject.

The early symptoms of the disease, beginning a day or two after the ingestion of pork, are those of a mild gastroenteritis. Later symptoms coincide with invasion of muscle by larvae. The latter begin about the end of the first week and may last for 4 to 6 weeks. Low-grade fever, pain and tenderness of muscles, edema of the conjunctiva and particularly of the eyelids, and fatigue are the usual manifestations. The myopathic aspects of *Trichinella* infestation are considered fully on page 1202.

Particularly heavy infestation may be associated with a CNS disorder. Headache, stiff neck, and a mild confusion state are the usual symptoms. Delirium, coma, hemiplegia, and aphasia have also been observed on occasion. The spinal fluid is usually normal but may contain a moderate number of lymphocytes and, rarely, parasites.

An eosinophilic leukocytosis usually appears when the muscles are invaded. Serologic (precipitin) and skin tests become positive early in the third week. The heart is often involved, manifested by tachycardia and electrocardiographic changes; sterile brain embolism may follow the myocarditis. These findings may aid in the diagnosis, which can be confirmed by finding the larvae in a muscle biopsy, using the technique of low-power scan of wet tissue pressed between two glass slides.

Trichinosis is seldom fatal. Most patients recover completely, although myalgia may persist for several months. Once recurrent seizures and focal neurologic deficits appear, they may persist indefinitely. The latter are based on the rare occurrence of a trichina

encephalitis (the filiform larvae may be seen in cerebral capillaries and in cerebral parenchyma) and emboli from mural thrombi arising in infected heart muscle.

*Treatment* In the treatment of trichinosis, thiabendazole, an antihelminthic agent, and corticosteroids are of particular value. Thiabendazole, 25 mg/kg twice daily for 5 to 7 days, is effective in both the enteral and parenteral phases of the disease. This drug prevents larval reproduction and is therefore useful in patients known to have ingested trichinous meat. It also interferes with the metabolism of muscle-dwelling larvae. Fever, myalgia, and eosinophilia respond well to the anti-inflammatory and immunosuppressant effects of prednisone (40 to 60 mg daily), and a salutary effect has been noted on the cardiac and neurologic complications as well.

Other nematodes, mainly toxocara (the cause of visceral larva migrans), strongyloides, and angiostrongyloides may rarely migrate to the brain, but each is characterized by a systemic illness, which is far more common than the neurologic one. Parasitic meningitis is discussed below.

**Diseases Due to Cestodes** (Table 32-6)

**Cysticercosis** This is the larval or intermediate stage of infection with the pork tapeworm *Taenia solium*. In Central and South America and in parts of Africa and the Middle East, cysticercosis is a leading cause of epilepsy and other neurologic disturbances. Because of a considerable emigration from these endemic areas, patients with cysticercosis are now being seen with some regularity in countries where the disease had previously been unknown. Usually the diagnosis can be made by the presence of multiple calcified lesions in the thigh, leg, and shoulder muscles and in the cerebral.

The cerebral manifestations of cysticercosis are diverse, related to the encystment and subsequent calcification of the larvae in the cerebral parenchyma, subarachnoid space, and ventricles (Fig. 32-8). The lesions are most often multiple but may be solitary. Before the cyst degenerates and eventually calcifies, CT scanning and MRI may actually visualize the scolex. Most often the neurologic disease presents with seizures, although many patients are entirely asymptomatic, the cysts being discovered radiologically. It is only when the cyst degenerates, many months or years after the initial infestation, that an inflammatory and granulomatous reaction is elicited and focal symptoms arise.

In some patients, a large subarachnoid or intraventricular cyst may obstruct the flow of CSF, in which case the surgical removal of the cyst or a shunt procedure becomes necessary. Proano and colleagues, however, have reported on a series of such cases with cysts larger than 5 cm in diameter, which they have treated medically. In a more malignant form of the disease, the cysticerci are located in the basilar subarachnoid space, where they induce an
intense inflammatory reaction leading to hydrocephalus, vasculitis, and stroke as well as cranial nerve palsies. This so-called racemose form of the illness is little altered by the use of praziquantel or any other form of therapy (Estanol et al).

**Treatment** The therapy of this disorder has been greatly improved in recent years by the use of CT and MRI and the administration of praziquantel, an antihelminthic agent that is also active against all species of schistosomes. The usual dose of praziquantel is 50 mg/kg of body weight, given orally daily for 15 to 30 days, depending upon the extent and activity of the lesions. Albendazole (5 mg/kg tid for 15 to 30 days), an alternative treatment, is believed by some to be more effective. Initially, treatment may seem to exacerbate neurologic symptoms, with an increase in cells and protein in the CSF, but then the patient improves and may become asymptomatic, with a striking decrease in the size and number of cysts on CT scanning. Corticosteroids may be useful if a large single lesion is causing symptoms by its mass effect.

**Other Cestode Infections** Infection with *Echinococcus* occasionally affects the brain. The usual sources of infection are water and vegetables contaminated by canine feces. After they are ingested, the ova hatch and the freed embryos migrate, primarily to lung and liver, but sometimes to brain (approximately 2 percent of cases), where a large solitary (hydatid) cyst may be formed. The typical lesion is a large fluid-filled cyst with the parasite visible by imaging procedures, but a solid nodular brain lesion, a “chitinoma,” is also known to occur. We have also observed a compressive spinal cord lesion. Treatment with the drug mebendazole is recommended when surgery is not feasible.

Cerebral coenurosis (*Coenurus cerebralis*) is an uncommon infestation by larvae of the tapeworm *Taenia multiceps*. It occurs mainly in sheep-raising areas where there are many dogs, the latter being the definitive hosts. The larvae form grape-like cysts, most often in the posterior fossa, which obstruct the spinal fluid pathways and cause signs of increased intracranial pressure. Surgical removal is possible.

Another cestode, *Spirometra mansoni*, may migrate within the brain, leaving a visible track as it moves. Subcutaneous nodules are the most common lesions. This parasite is found predominantly in the Far East.

The nervous system may also be invaded directly by certain worms (*Ascaris, Filaria*) and flukes (*Schistosoma, Paragonimus*). These diseases are virtually nonexistent in the United States except among those who have recently returned from endemic areas. Schistosomiasis, however, is of such great importance and often invades the nervous system in such characteristic ways that it is considered below in detail.

**Diseases Caused by Trematodes**

(Table 32-6 and page 1062)

**Schistosomiasis** The ova of trematodes seldom involve the nervous system, but when they do, the infecting organism is usually *Schistosoma japonicum* and, less often, *Schistosoma haematobium* or *Schistosoma mansoni*. It is said that *Schistosoma japonicum* has a tendency to localize in the cerebral hemispheres and *S. mansoni* in the spinal cord, but there have been many exceptions. The cerebral lesions form in relation to direct parasitic invasion of blood vessels and take the form of mixed necrotizing and ischemic parenchymal foci that are infiltrated by eosinophils and giant cells (Scrimgeour and Gajdusek). The lesions do not calcify.

Schistosomiasis is widespread in tropical regions, especially in the Nile Valley of Egypt; North American neurologists have little contact with it except in travelers who have bathed in lakes or rivers where the snail hosts of the parasite are plentiful. The initial manifestation is often a local skin irritation at the site of entry of the parasite (swimmer’s itch), but the patient frequently does not offer this information unless sought. An estimated 3 to 5 percent of patients develop neurologic symptoms several months after exposure. Headaches, convulsions (either focal or generalized), and other cerebral signs appear; with lesions of larger size, papilledema may develop, simulating a brain tumor.

Some types of *Schistosoma* infection (also called *Bilharzia*), mainly *mansoni*, tend to localize in the spinal cord, causing an acute or subacute myelitis that is concentrated in the conus medullaris. The clinical picture is of a subacutely developing transverse cord lesion. There is often preceding leg or radicular pain and bladder control is affected prominently. This is one of the most frequent forms of myelitis in Brazil and other parts of South America. We have observed a few cases in students returning from Africa; their lesions were in the conus. Unless treated immediately, there may be permanent paralysis of the legs and bladder from inflammatory and microvascular destruction of the lower cord.

Examination of the CSF in the myelitic form discloses a pleocytosis, sometimes with an increase in eosinophils (more than half of patients), increased protein content, and sometimes increased pressure. Biopsy of the liver and rectal mucosa, skin tests, and complement fixation tests confirm the diagnosis. The role of serologic tests has not been clearly established.

The other major trematode, *Paragonimus*, has been known rarely to invade the brain, where it creates a solitary granulomatous nodule comparable to that seen in schistosomiasis.

**Treatment** This consists of praziquantel orally in a dosage of 20 mg/kg tid. In one series, 8 of 9 patients with epilepsy due to cerebral schistosomiasis became seizure-free after treatment with praziquantel. Surgical excision of spinal granulomatous tumors is sometimes indicated, but the results are unpredictable.
Eosinophilic Meningoencephalitis Due to Parasites  An eosinophilic meningoencephalitis, often with cranial nerve and painful polyradicular findings, has been reported with *Angiostrongylus cantonensis*, *Gnathostoma spinigerum*, *Paragonimus westermani*, and *Toxocara canis* and *cati* infections. In *Angiostrongylus* infections, snails, freshwater prawns, and unwashed lettuce carry the nematode. The resulting illness may last for weeks to months, with pain, paresthesias, sensorimotor abnormalities, and a confusional state as the main manifestations. Cook has reviewed these and other protozoan and helminthic infections of the CNS. An interesting outbreak in a group of medical students who returned to the United States from Jamaica has been described by Slom and colleagues; they highlight paresthesias and dysesthesias but have noted the presence of eosinophilia in the blood or CSF in only half of their patients. Hodgkin disease, other lymphomas, and cholesterol embolus will also occasionally incite an eosinophilic meningitis.

More detailed descriptions of parasitic diseases of the nervous system can be found in the monographs of Bia and of Gutierrez.

CHAPTER 33

VIRAL INFECTIONS OF THE NERVOUS SYSTEM, CHRONIC MENINGITIS, AND PRION DISEASES

VIRAL INFECTIONS OF THE NERVOUS SYSTEM

A number of viruses share the unique tendency to affect primarily the human nervous system. Included in this group are the human immunodeficiency viruses (HIV-1 and HIV-2), herpes simplex viruses (HSV-1 and HSV-2), herpes zoster or varicella zoster virus (VZV), Epstein-Barr virus (EBV), cytomegalovirus (CMV), poliovirus, rabies, and several seasonal arthropod-borne viruses. Some of these are neurotropic, exhibiting an affinity for certain types of neurons: for example, poliovirus enters motor neurons, VZV and peripheral sensory neurons, rabies virus and brainstem neurons, and others. For many of the rest of the neurotropic viruses, the affinity is less selective in that they involve all elements of the nervous system—that is, they are neurohistiopathic. Herpes simplex, for example, may devastate the medial parts of the temporal lobes, destroying neurons, glial cells, myelinated nerve fibers, and blood vessels; and HIV, the cause of the acquired immunodeficiency syndrome (AIDS), may induce multiple foci of tissue necrosis throughout the cerebrum.

These relationships and many others, which are the subject matter of this chapter, are of wide interest in medicine. In many of these conditions, the systemic effects of the viral infection are negligible; it is the neurologic disorder that brings them to medical attention. In other words, the neural aspects of viral infection may assume a clinical importance that is disproportionate to the systemic illnesses. This aspect of neurology must therefore also be familiar to pediatricians and internists, who are likely to be the first to see such patients.

A detailed discussion of viral morphology and cell-virus interactions is beyond the scope of a textbook of neurology. Authoritative overviews of this subject can be found in the current edition of *Harrison’s Principles of Internal Medicine* and in the introductory chapters of R. T. Johnson’s monograph *Viral Infections of the Nervous System*.

Pathways of Infection

Viruses gain entrance to the body by one of several pathways. Mumps, measles, and VZV enter via the respiratory passages. Polioviruses and other enteroviruses enter by the oral-intestinal route, and HSV, mainly via the oral or genital mucosal route. Other viruses are acquired by inoculation, as a result of the bites of animals (e.g., rabies) or mosquitoes (arthropod-borne or arbovirus infections). The fetus may be infected transplacentally by rubella virus, CMV, and HIV.

Following entry into the body, the virus multiplies locally and in secondary sites and usually gives rise to a viremia. Most viruses are prevented from entering central nervous system (CNS) tissues, presumably by the blood-brain barrier. Moreover, most antibodies and immunocompetent cells are excluded as well, so that the same mechanism that limits the entry of viruses also deters their removal. Viral particles are cleared from the blood by the reticuloendothelial system; but if the viremia is massive or other conditions are favorable, they will invade the CNS probably via the cerebral capillaries and the choroid plexuses.

Another pathway of infection is along peripheral nerves; centripetal movement of virus is accomplished by the retrograde axoplasmic transport system. Herpes simplex, VZV, and rabies viruses utilize this peripheral nerve pathway, which explains why the initial symptoms of rabies (and the similar but rare B-virus infection of monkeys) occur locally, at a segmental level corresponding to the animal bite. In animals inoculated subcutaneously with VZV, sensitive DNA amplification techniques identify fragments of viral genome only in the dorsal root ganglion or ganglia corresponding to the dermatome(s) containing the site of inoculation. It has been shown experimentally that HSV may spread to the CNS by involving olfactory neurons in the nasal mucosa; the central processes of these cells pass through openings in the cribriform plate and synapse with cells in the olfactory bulb (CNS). Another potential pathway is the trigeminal nerve and gasserian ganglion. However, the role of these pathways in human infection is not certain. Of these different routes of infection, the hematogenous one is by far the most important for the majority of viruses. The steps in the hematogenous spread of infection include crossing the blood-brain barrier through small vessels of the brain and the choroid plexus. Viruses cross both within migrating lymphocytes and directly through areas of glial and vascular regions that are permeable to the organisms.

Mechanisms of Viral Infections

Viruses, once they invade the nervous system, have diverse clinical and pathologic effects. One reason for this diversity is that different cell populations within the CNS vary in their susceptibility to infection with different viruses. To be susceptible to a viral infection, the host cell must have on its cytoplasmic membrane specific receptor sites to which the virus attaches. Thus, some infections are confined to meningeal cells, enteroviruses being the most common, in which case the clinical manifestations are those of aseptic meningitis. Other viruses will involve particular classes of neurons of the brain or spinal cord, giving rise to the more serious disorders such as encephalitis and poliomyelitis, respectively. In some viral infections, the susceptibility of particular cell groups is even more specific. In poliomyelitis, for example, motor neurons of cranial and spinal nerves are particularly vulnerable; in rabies, there is an affinity for neurons of the trigeminal ganglia, cerebellum, and lim-
bic lobes. The virus or its nucleocapsid must be capable of penetrating the cell, mainly by the process of endocytosis, and of releasing its protective nucleoprotein coating. For viral reproduction to occur, the cell must have the metabolic capacity to transcribe and translate virus-coated proteins, to replicate viral nucleic acid, and, under the direction of the virus’s genome, to assemble viroids.

Also, the pathologic effects of viruses on susceptible cells vary greatly. Acute encephalitis, susceptible neurons are invaded directly by virus and the cells undergo lysis. There is an appropriate glial and inflammatory reaction. Neuronophagia (phagocytosis of affected neurons and their degenerative products by microglia) is a mark of this phenomenon. In progressive multifocal leukoencephalopathy (PML), there is a selective lysis of oligodendrocytes, resulting in foci of demyelination. With other viral infections, zones of tissue necrosis of gray and white matter occur, and these changes may localize in particular regions, e.g., in the inferomedial parts of the temporal lobes in cases of HSV encephalitis. VZV and HSV may remain latent in neurons of the sensory ganglia for long periods, until some factor triggers reactivation and retrograde spread of virus to cutaneous dermatomes or mucocutaneous epithelium. Only then will the inflammatory reaction to viral replication create symptoms (pain, weakness, sensory loss). In certain congenital infections, e.g., rubella and CMV, the virus persists in nervous tissue for months or years. Differentiating cells of the fetal brain have particular vulnerabilities, and viral incorporation may give rise to malformations and to hydrocephalus (e.g., mumps virus with ependymal destruction and aqueductal stenosis).

In experimental animals, cerebral neoplasms can be induced when the viral genome is incorporated into the DNA of the host cell. There is suggestive evidence of such a mechanism in humans (relating to EBV in B-cell lymphoma of the brain). In still other circumstances, a viral infection may exist in the nervous system for a long period before exciting an inflammatory reaction (e.g., progressive multifocal encephalopathy; subacute sclerosing panencephalitis); in these cases it may be so indolent as to simulate a degenerative disease.

**CLINICAL SYNDROMES**

A large number of viruses are able to affect the nervous system. Among the enteroviruses alone, nearly 70 distinct serologic types have been associated with CNS disease, and additional types from this family of viruses and others are still being discovered. There is no need, however, to consider these viruses individually, since there are only a limited number of ways in which they express themselves clinically. Seven syndromes occur with regularity and should be familiar to neurologists: (1) acute aseptic (“lymphocytic”) meningitis; (2) chronic meningitis; (3) acute encephalitis or meningoencephalitis, which may be generalized or focal; (4) herpes zoster ganglionitis; (5) chronic invasion of nervous tissue by retroviruses, i.e., the AIDS syndrome and tropical spastic paraparesis (TSP); (6) acute anterior poliomyelitis; and (7) chronic viral infections (“slow infections”). The last group is presently distinguished from infections with the unique prion agents, which are discussed later in the chapter.

**THE SYNDROME OF ACUTE ASEPTIC MENINGITIS**

The term aseptic meningitis was first introduced to designate what was thought to be a specific disease—“aseptic” because bacterial cultures were negative. The term is now applied to a symptom complex that is produced by any one of numerous infective agents, the majority of which are viral (but a few of which are bacterial—mycoplasma, Q fever, other rickettsial infections, etc.). Since aseptic meningitis is rarely fatal, the precise pathologic changes are uncertain but are presumably limited to the meninges. Conceivably, there may be some minor changes in the brain itself, but these are of insufficient severity to cause neurologic symptoms and signs or to alter the results of computed tomography (CT) or magnetic resonance imaging (MRI).

In outline, the clinical syndrome of aseptic meningitis consists of fever, headache, signs of meningeal irritation, and a predominantly lymphocytic pleocytosis with normal cerebrospinal fluid (CSF) glucose. Usually the onset is acute and the temperature is elevated, from 38 to 40°C (100.4 to 104°F). Headache, perhaps more severe than that associated with other febrile states, is the most frequent symptom. A variable degree of lethargy, irritability, and drowsiness may occur; confusion, stupor, and coma mark the case as an encephalitis rather than a meningitis. Photophobia and pain on movement of the eyes are common additional complaints. Stiffness of the neck and spine on forward bending attests to the presence of meningeal irritation (meningismus), but at first it may be so slight as to pass unnoticed. Here the Kernig and Brudzinski signs help very little, for they are often absent in the presence of manifest viral meningitis. When there are accompanying neurologic signs, they too tend to be mild or fleeting: paresthesias in an extremity, isolated strabismus and diplopia, a slight inequality of reflexes, or wavering Babinski signs. Other symptoms and signs are infrequent and depend mainly on the systemic effects of the invading virus; these include sore throat, nausea and vomiting, vague weakness, pain in the back and neck, conjunctivitis, cough, diarrhea, vomiting, rash, adenopathy, etc. The childhood exanthems associated with meningitis and encephalitis (varicella, rubella, mumps) produce well-known eruptions and other characteristic signs. An erythematous papulomacular, nonpuritic rash, confined to the head and neck or generalized, may also be a prominent feature (particularly in children) of certain echoviruses and Coxsackie viruses. An enanthem (herpangina), taking the form of a vesiculoulcerative eruption of the buccal mucosa, may also occur with these viral infections.

The CSF findings consist of a pleocytosis (mainly mononuclear except in the first days of the illness, when more than half the cells may be neutrophils), and a small and variable increase in protein. In milder cases, in the first hours or day of the illness, there may be no abnormalities of the spinal fluid, and the patient may erroneously be thought to have migraine or a headache induced by a systemic infectious illness. Micro-organisms cannot be demonstrated by conventional smear or bacterial culture. As a rule, the glucose content of the CSF is normal; this is important because a low glucose concentration in conjunction with a lymphocytic or mononuclear pleocytosis usually signifies tuberculous or fungal meningitis or certain noninfectious disorders such as carcinomatous or lymphomatous invasion, or sarcoid of the meninges. Infrequently, a mild depression of the CSF glucose (never below 25 mg/dL) has been reported with the meningitis caused by mumps, HSV-2, lymphocytic choriomeningitis, or VZV.

**Causes of Acute Aseptic Meningitis**

Aseptic meningitis is a common occurrence, with an annual incidence rate of 11 to 27 cases per 100,000 population (Beghi et al;
Most are due to viral infections. Of these, the most common are the enteroviral infections—echovirus and Coxsackie virus. These make up 80% of cases of aseptic meningitis in which a specific viral cause can be established. Mumps is perhaps next in frequency, followed by HSV-2, lymphocytic choriomeningitis (LCM), and adenovirus infections. EBV (infectious mononucleosis), CMV, leptospirosis, HSV-1, and the bacterium Mycoplasma pneumoniae (see Chap. 32). Influenza virus, adenoviruses, and numerous sporadic and otherwise innocuous agents have at times been isolated from the spinal fluid in cases of aseptic meningitis. The California and West Nile viruses, which are arthropod-borne viruses (“arthroviruses”), are responsible for a small number of cases (usually the arboviruses cause an encephalitis or meningoencephalitis, as discussed further on). Rarely, the icteric stage of infectious hepatitis is preceded by mild meningitis, the nature of which becomes evident when the jaundice appears. All these viral infections, particularly those due to the enteroviruses—together with mycoplasmal infection, leptospirosis, and Lyme borreliosis—account for the largest proportion of infectious cases of aseptic meningitis in which the etiology can be established, the remainder being due to tuberculosis, fungal infections and rarer organisms. Chronic and recurrent meningitis constitutes a special problem, discussed below.

It is now well recognized that infection with HIV may present as an acute, self-limited aseptic meningitis with an infectious mononucleosis-like clinical picture. While HIV has been obtained from the CSF in the acute phase of the illness, seroconversion occurs only later, during convalescence from the meningitis (see further on in this chapter). HSV-1 has been isolated from the CSF of patients with recurrent bouts of benign aseptic meningitis (so-called Mollaret meningitis), but this finding has not been consistent (Steel et al). As discussed in Chap. 47, it is now believed that this virus also underlies many if not most cases of what has been traditionally considered idiopathic Bell’s palsy.

Finally, two other aspects of the virology of aseptic meningitis should be noted; first, in every published series of cases from virus isolation centers, a specific cause cannot be established in one-third or more of cases of presumed viral origin; second, most agents capable of producing aseptic meningitis also sometimes cause encephalitis.

Differential Diagnosis of Viral Meningitis

Clinical distinctions between the many viral causes of aseptic meningitis cannot be made with a high degree of reliability, but useful leads can be obtained by attention to certain details of the clinical history and physical examination. It is important to inquire about recent respiratory or gastrointestinal symptoms, immunizations, past history of infectious disease, family outbreaks, insect bites, contact with animals, and areas of recent travel. The presence of a local epidemic, the season during which the illness occurs, and the geographic location are other helpful data.

As already mentioned, the enteroviruses (echo, Coxsackie and, in underdeveloped countries, polio) are by far the commonest causes of viral meningitis. Because these organisms grow in the intestinal tract and are spread mainly by the fecal-oral route, family outbreaks are usual and the infections are most common among children. A number of echovirus and Coxsackie virus (particularly group A) infections are associated with exanthema and may, in addition, be associated with the grayish vesicular lesions of oral herpangina. Pleurodynia, brachial neuritis, pericarditis, and orchitis are characteristic of some cases of group B Coxsackie virus infections (but there are certainly other causes). Pain in the back and neck and in the muscles should suggest polyarthralgia. Lower motor neuron weakness may occur with echo and Coxsackie virus infections, but it is usually mild and transient in nature. The peak incidence of enteroviral infections is in August and September. This is true also of infections due to arboviruses, but as a rule the latter cause encephalitis rather than meningitis.

Mumps meningitis occurs sporadically throughout the year, but the highest incidence is in late winter and spring. Males are affected three times more frequently than females. Other manifestations of mumps infection—parotitis, orchitis, mastitis, oophoritis, and pancreatitis—may or may not be present. It should be noted that orchitis is not specific for mumps but occurs occasionally with group B Coxsackie virus infections, infectious mononucleosis, and lymphocytic choriomeningitis. A definite past history of mumps aids in excluding the disease, since an attack confers lifelong immunity.

The natural host of the LCM virus is the common house mouse, Mus musculus. Humans acquire the infection by contact with infected hamsters or with dust contaminated by mouse excreta. Laboratory workers who handle rodents may be exposed to LCM. The meningitis may be preceded by respiratory symptoms (sometimes with pulmonary infiltrates). The infection is particularly common in late fall and winter, presumably because mice enter dwellings at that time. Wild rodents may also be the source of the so-called encephalomyocarditis virus infection, and cats, of course, of bacterial cat-scratch disease.

The infectious agent in leptospirosis is a spirochete, but the clinical syndrome that it produces is indistinguishable from viral meningitis (discussed in Chap. 32). Infection is acquired by contact with soil or water contaminated by the urine of rats and also of dogs, swine, and cattle. Although leptospirosis may appear in any season, its incidence in the United States shows a striking peak in August. The presence of conjunctival suffusion, a transient blotchy erythema, severe leg and back pain, and pulmonary infiltrates should suggest leptospiral infection.

A more common spirochetal cause of aseptic meningitis (and meningoencephalitis) is Lyme borreliosis. This is now the most common vector (tick)-borne disease in the United States. Most cases occur in the northeastern states, Minnesota, and Wisconsin during the months of May to July—the questing time among nymphal ixodid ticks. In 60 to 80 percent of patients, a bright-red annular skin lesion at the site of the tick bite, often with secondary annular lesions, precedes the onset of meningeal signs (as discussed more extensively on page 618). There may be associated facial palsy, cauda equina symptoms such as urinary retention and sacral numbness, or a sensory neuropathy (see Chap. 46).

The atypical pneumonias agents M. pneumoniae and Q fever (Coxiella burnetti) can also produce an aseptic meningitis that is indistinguishable from the viral form.

In the context of an aseptic meningitis, the presence of sore throat, generalized lymphadenopathy, transient rash, and mild icterus is suggestive of infectious mononucleosis due to EBV or, at times, CMV infection. Icterus is a prominent manifestation of viral hepatitis and some serotypes of leptospirosis and, at times, of Q fever.

A mononucleosis type of infection (fever, rash, arthralgias, lymphadenopathy) in an individual with recent sexual exposure to a potentially infected partner or a known carrier of HIV—or with
exposure to contaminated blood—should always raise the possibility of HIV infection. As with Lyme and HSV, HIV meningoencephalitis may be additionally associated with a cauda equina neuritis, as discussed in Chap. 46. In the case of HSV, there is often a preceding genital infection with the virus.

Aside from viral isolation and serologic tests and, more recently, detection by polymerase chain reaction (see further on), few laboratory examinations are helpful. The peripheral white cell count is usually normal but may sometimes be slightly elevated or depressed, with a mild lymphocytosis. Eosinophilia should suggest a parasitic infection. Most cases of infectious mononucleosis can be identified by the blood smear and specific serologic tests (hemagglutinins or others). LCM should be suspected if there is an intense pleocytosis. Counts above 1000 mononuclear cells per cubic millimeter in the spinal fluid are most often due to LCM but may occur occasionally with mumps or echovirus 9; in the latter, neutrophils may predominate in the CSF for a week or longer. Slightly depressed glucose in the spinal fluid is consistent with mumps meningitis and with the viruses mentioned earlier, but it always is a worrisome sign of bacterial or fungal infection.

Liver function tests are abnormal in many patients with EBV infection, leptospiral infections, and amnestic hepatitis. In the majority of patients with M. pneumoniae infections, cold agglutinins appear in the serum toward the end of the first week of the illness. Panels of serologic tests for the main viruses that cause aseptic meningitis are available; most use complement fixation or enzyme-linked immunosorbent assay (ELISA) techniques; an infection is demonstrated by a fourfold increase in titer from acute to convalescent serum drawn at least 10 days apart, but these, of course, do no more than confirm the diagnosis after the illness has mostly passed. Serologic reactions of CSF for syphilis should be interpreted with caution, because inflammation of many types, including infectious mononucleosis, can produce a false-positive reaction. In the last few years, the polymerase chain reaction (PCR) has been applied to the diagnosis of viral infections of the nervous system, among them CMV and HSV. The test detects portions of viral DNA in the spinal fluid and is most sensitive during the active stage of viral replication, in contrast to serologic tests, which are more accurate later in the course of the infection. There are numerous false-negative and fewer false-positive PCR tests for CMV, but they are nonetheless useful in some circumstances, such as the early diagnosis of fulminant infection in AIDS patients (see later in this chapter).

Other Causes of Aseptic, Chronic, and Recurrent Meningitis

Several other categories of disease may cause an apparently sterile, predominantly lymphocytic or mononuclear reaction in the leptomeninges, and these should be considered in cases that do not conform to the usual pattern: (1) foci of bacterial infection lying adjacent to the meninges; (2) partially treated bacterial meningitis; (3) specific meningeal infections in which the organism is difficult or impossible to isolate—fungal and tuberculous meningitides are at times in this category, and the group also includes parasitic infections; (4) neoplastic invasion of the leptomeninges (lymphomatous and carcinomatous meningitides); (5) granulomatous, vasculitic, or other inflammatory diseases such as sarcoidosis, Behçet disease, and granulomatous angiitis; and (6) acute or chronic recurrent inflammatory meningitides of unusual or obscure origin. The last of these constitutes a vexing group in which no cause can initially be found, but, as indicated further on, careful follow-up and repeated CSF examinations, or in some cases meningeal biopsy, will reveal in the nature of a few, and many others will resolve spontaneously. They are described below, under “Chronic Persistent and Recurrent Meningitis.”

Other occasional causes include an aseptic chemical meningitis incited by rupture of a craniopharyngioma or other cystic structure containing proteinaceous fluid or the introduction of a foreign substance to the subarachnoid space, but the cause in these instances is usually obvious. We had a case that followed the instillation of hypertonic saline (Ratz procedure) for the relief of arachnoidal adhesions after back surgery. Also, an idiosyncratic, presumably immunologic meningitis has resulted from the use of nonsteroidal anti-inflammatory drugs, intravenous immune globulin (actually a carrier chemical in the solution), and, rarely, from other drugs.

In respect to the first two categories, parameningeal and partially treated bacterial infections and a smoldering parasanal sinusitis or mastoiditis may produce a CSF picture of aseptic meningitis because of intracranial extension (epidural or subdural infection). It must also be remembered that antibiotic therapy given for a systemic or pulmonary infection may suppress a bacterial meningitis to the point where mononuclear cells predominate, glucose is near normal, and organisms cannot be cultured from the CSF (although they may still be evident by Gram’s stain). Careful attention to the history of recent antimicrobial therapy permits recognition of these cases. Rarely, children with scarlet fever or streptococcal pharyngitis have been noted to develop meningeal signs and pleocytosis, the result of a sterile serous inflammation that does not involve invasion of the meninges by organisms. The same may occur in subacute bacterial endocarditis. Syphilis, cryptococcosis, and tuberculosis are the important members of the third group in which the organism may be difficult to culture, as detailed in Chap. 32. Tuberculous meningitis, in its initial stages, may masquerade as an innocent aseptic meningitis; the diagnosis may be delayed because the tubercle bacillus is difficult to find in stained smears, and cultures may require several weeks. Typically, the CSF glucose is severely depressed, although it may be only slightly reduced early in the illness. Similarly, the diagnosis of cryptococcosis, other fungal infection, or nocardiosis is occasionally missed because the organisms may be present in such low numbers as to be overlooked in smears, especially in AIDS patients. Brucellosis (Mediterranean fever, Malta fever) is a rare disease, practically confined to the Middle East, that may present as an acute meningitis or meningoencephalitis, with the CSF findings of an aseptic meningitis. The diagnosis depends on the detection of high serum antibody titers and Brucella-specific immunoglobulins, using the ELISA.

In the fourth (neoplastic) group, leukemias and lymphomas are the most common sources of meningeal reactions. In children, a leukemic “meningitis” with cells (lymphoblasts or myeloblasts) in the CSF numbering in the thousands occurs frequently in the late stages of the illness. In carcinomatous meningitis, neoplastic cells extend throughout the leptomeninges and involve cranial and spinal nerve roots, producing a picture of meningoarachnitis with normal or low CSF glucose values. Lymphocytic meningitis that is accompanied by cranial nerve palsies often turns out to be tuberculous if the patient is febrile and the CSF glucose is low; it is likely to be neoplastic if the patient is afebrile and the CSF glucose is normal or mildly decreased. Concentrated cytologic preparations usually permit identification of the tumor cells. These diseases are discussed in detail in Chap. 31.
Sarcoidosis, Behçet disease, intravascular lymphoma, and granulomatous angiitis are the best-known examples of a group of noninfectious inflammatory meningitides. Occlusion of many small cerebral blood vessels by cholesterol emboli may also excite a reaction in meningeal vessels and a pleocytosis that includes eosinophils. Each of these conditions can present with a clinical picture of meningitis alone, but more often there are indications of both meningeal and parenchymal involvement.

**Chronic Persistent and Recurrent Meningitis** (Table 33-1)

Chronic and recurrent meningitides of obscure etiology always pose diagnostic problems. Such patients may have a low-grade fever, headache of varying severity, and stiff neck and a predominantly mononuclear pleocytosis, sometimes with slightly raised CSF pressure. There may also be minor focal neurologic signs. A viral or some other type of infective inflammation is always suspected, but a search by culture methods and serology usually yields negative results. Herpesvirus has been demonstrated to be the cause expected, but a search by culture methods and serology usually yields negative results. Herpesvirus has been demonstrated to be the cause in many cases as in the recurrent Mollaret type noted below. Sometimes the process improves without identification of the cause over a period of months or a year or more; in other cases, the cause is eventually found. Only a few end fatally. In a series of such patients studied at the Mayo Clinic, 33 of 39 underwent a natural resolution of the process, which proceeds without identification of the cause over weeks, months or years. The outcome and response to steroids in our cases and other reported series has been much the same. These series excluded chemical or irritative meningitis, which should be considered if there has been spinal surgery or infusion of even apparently innocuous substances into the spinal space.

The special problem of *chronic neutrophilic meningitis* has been mentioned on page 622. It is usually attributable to *Nocardia, Aspergillus, Actinomyces*, or certain *Mycobacterium* species (see Peacock, cited in the preceding chapter).

Our practice in the management of patients with chronic meningitis is to repeat the lumbar puncture several times in order to obtain cultures and cytology of CSF, using markers to detect uniform populations of B and T lymphocytes and tumor cells, a biochemical test that is sensitive to neoplastic meningitis (such as β₂-microglobulin), PCR for amplification of herpesviruses, serologic tests for HIV, syphilis, Lyme disease, *Brucella*, etc.; MRI of the brain and spinal cord with gadolinium should also be performed. If hydrocephalus develops, it should be managed along the lines described in Chap. 30. A trial of antiviral agents and broad-spectrum antibiotics seems reasonable, although we have had no success with them in our last several patients. We resort to a biopsy of the meninges if the diagnosis has not been clarified in 6 to 12 months or if a febrile meningitis persists for more than several weeks, but this practice has proved to be of limited value. In Andersen’s series, mentioned above, biopsy yielded a diagnosis in 5 of 25 patients. Finally, if bacterial infection has been reasonably excluded, we try corticosteroids for several weeks or longer and then attempt to taper the dose while observing the patient and re-checking the CSF formula.

The CSF formula, in a number of other chronic or acutely recurring diseases of obscure origin, corresponds to that of aseptic meningitis: (1) The Vogt-Koyanagi-Harada syndrome, which is characterized by combinations of iridocyclitis, depigmentation of a hair strand (poliosis circumscripta) and skin around the eyes, loss of eyelashes, dysacusis, and deafness. The course is quite benign, and the pathologic basis of the syndrome is not known. (2) Mollaret recurrent meningitis, some (perhaps most) instances of which have been associated with HSV-1 (Steel) and some with HSV-2 infection (Cohen et al). These episodes of acute meningitis, with severe headache and sometimes low-grade fever, lasting for about 2 weeks, may recur for a period of several months or many years. In a few such patients of ours, in whom no virus could be identified in the CSF, antiviral therapy met with little success, although corticosteroids seemed to reduce the severity of acute episodes, as mentioned above. A proportion of these cases follow bouts of genital herpes. (3) Allergic or hypersensitivity meningitis, occurring in the course of serum sickness and of connective tissue diseases, such as lupus erythematosus, and in relation to certain medications such as nonsteroidal anti-inflammatory drugs and intravenously administered immunoglobulin; and (4) Behçet disease, which is an important acute, recurrent inflammatory CNS disease. It is essentially a diffuse inflammatory disease of small blood vessels and is more appropriately considered with the vasculitides (page 733).

In summary, the history of the illness, the associated clinical findings, and the laboratory tests usually provide the clues to the diagnosis of nonviral and chronic forms of aseptic meningitis. It is

always important to keep in mind the possibility of neoplasia, HIV, tuberculosis, cryptococcosis, sarcoidosis, syphilis, borreliosis, and inadequately treated bacterial meningitis—each of which may simulate aseptic meningitis and each of which presents an urgent diagnostic problem. By contrast, the various viral forms of aseptic meningitis are usually self-limited and benign; establishing a specific etiologic diagnosis is usually not necessary.

THE SYNDROME OF ACUTE ENCEPHALITIS

From the foregoing discussion it is evident that the separation of the clinical syndromes of aseptic meningitis and encephalitis is not always easy. In some patients with aseptic meningitis, mild drowsiness or confusion may be present, suggesting cerebral involvement. Conversely, in some patients with encephalitis, the cerebral symptoms may be mild or inapparent, and meningeal symptoms and CSF abnormalities predominate. These facts make it difficult to place complete reliance on statistical data from various virus laboratories about the relative incidence of meningitis and encephalitis. The common practice is to assume that viral meningitis causes only fever, headache, stiff neck, and photophobia; if any other CNS symptoms are added, the condition is generally called meningoencephalitis. As has been emphasized, it appears that the same spectrum of viruses gives rise to both meningitis and encephalitis. It is our impression that many cases of enteroviral and other CNS symptoms are added, the condition is generally called meningoencephalitis. Conversely, in some patients with encephalitis, the cerebral symptoms are the initial complaints and present a diagnostic problem. By contrast, the various viral forms of aseptic meningitis (mycoplasmal, rickettsial, Lyme, etc.) are considered in Chap. 32 (page 601) and should be reviewed with this section. According to the Centers for Disease Control and Prevention, about 20,000 cases of acute viral encephalitis are reported annually in the United States. Death occurs in 5 to 20 percent of these patients and residual signs such as mental deterioration, amnesic defect, personality change, recurrent seizures, and hemiparesis are seen in about another 20 percent. However, these overall figures fail to reflect the widely varying incidence of mortality and residual neurologic abnormalities that follow infection by different viruses. In herpes simplex encephalitis, for example, approximately 50 percent of patients die or are left with some impairment, and in eastern equine encephalitis, the figures are even higher. On the other hand, death and serious neurologic sequelae have been observed in only 5 to 15 percent of those with western equine and West Nile infections and in even lesser numbers of patients with Venezuelan, St. Louis, and La Crosse encephalitides.

As with aseptic meningitis, the number of viruses that can cause encephalitis or a postinfectious autoimmune reaction is sizable, and one might suppose that the clinical problems would be infinitely complex. However, the types of viral encephalitis that occur with sufficient frequency to be of diagnostic importance are relatively few. HSV is by far the commonest sporadic cause of encephalitis and has no seasonal or geographic predictions. Its age distribution is slightly skewed and biphasic, affecting persons mainly between ages 5 and 30 years and those over 50.

Many other viruses, exemplified by the arboviral encephalitides, have a characteristic geographic and seasonal incidence. The most important of these is the Japanese encephalitis serogroup (flaviviruses), of which the West Nile virus is a member. In recent outbreaks in the United States, the latter virus has been more frequent than any of the other arboviruses and has had a wide geographic distribution (Solomon). In the United States, eastern equine encephalitis, as the name implies, has been observed mainly in the eastern states and on both the Atlantic and Gulf coasts. Western equine encephalitis is fairly uniformly distributed west of the Mississippi River and in even lesser numbers of patients with Venezuelan, St. Louis, and La Crosse encephalitides.

**Etiology**

Whereas numerous viral, bacterial, fungal, and parasitic agents are listed as causes of the encephalitis syndrome, only the viral ones are considered here, for it is to these that one usually refers when the term encephalitis is used. The nonviral forms of encephalitis are discussed in Chap. 32 (page 601) and should be reviewed with this section. According to the Centers for Disease Control and Prevention, about 20,000 cases of acute viral encephalitis are reported annually in the United States. Death occurs in 5 to 20 percent of these patients and residual signs such as mental deterioration, amnesic defect, personality change, recurrent seizures, and hemiparesis are seen in about another 20 percent. However, these overall figures fail to reflect the widely varying incidence of mortality and residual neurologic abnormalities that follow infection by different viruses. In herpes simplex encephalitis, for example, approximately 50 percent of patients die or are left with some impairment, and in eastern equine encephalitis, the figures are even higher. On the other hand, death and serious neurologic sequelae have been observed in only 5 to 15 percent of those with western equine and West Nile infections and in even lesser numbers of patients with Venezuelan, St. Louis, and La Crosse encephalitides.
October, slightly later than is customary for the other arboviruses. Venezuelan equine encephalitis is common in South and Central America; in the United States it is practically confined to Florida and the southwestern states. California virus encephalitis predominates in the northern Midwest and northeastern states. After West Nile, the La Crosse variety is perhaps the most frequent identifiable arbovirus encephalitis in the United States.

Rabies infections occur worldwide, but in the United States they are seen mostly in the Midwest and along the West Coast. Japanese B encephalitis (the most common encephalitis outside of North America), Russian spring-summer encephalitis, Murray Valley encephalitis (Australian X disease), and several less common viral encephalitides are infrequent in the United States or, as in the case of West Nile fever, have appeared only recently. With the ease and rapidity of travel, many of these will undoubtedly increase in number in North America and parts of Europe where they have not been seen hitherto.

Infectious mononucleosis, which is a primary infection with EBV, is complicated by meningitis, encephalitis, facial palsy, or polyneuritis of the Guillain-Barré type in a small proportion of cases. Each of these neurologic complications can occur in the absence of the characteristic fevers, pharyngitis, and lymphadenopathy of infectious mononucleosis. The same is true of M. pneumoniae. In these two diseases there is still uncertainty as to whether they are true infectious encephalitides or postinfectious complications, as discussed in Chap. 32. Recent evidence from PCR testing of spinal fluid is consistent with a direct infection in some cases. Varicella zoster and CMV are other herpes-type viruses that may cause encephalitis. They are discussed in relation to the particular clinical settings in which they occur. Definite cases of “epidemic encephalitis” (encephalitis lethargica) have not been observed in acute form since 1930, though an occasional surviving patient with a residual parkinsonian syndrome is still seen in neurology clinics. However, various movement disorders including parkinsonism are being seen as a residua of encephalitis from the flaviviruses. The latency from infection to these complications is brief, or may be present from the outset, quite unlike encephalitis lethargica.

The relative frequency of the various viral infections of the nervous system can be appreciated from several studies. An early series from the Walter Reed Army Institute comprising 1282 patients is particularly noteworthy in that a positive laboratory diagnosis was achieved in more than 60 percent of cases (Buescher et al)—a higher rate than in almost any subsequent study of comparable size. Aside from the poliovirus (some of the data were gathered before 1959), the common infective agents in cases of both aseptic meningitis and encephalitis were group B Coxsackie virus, echovirus, mumps virus, lymphocytic choriomeningitis virus, arboviruses, HSV, and Leptospira, in that order. In a later prospective virologic study of all children examined at the Mayo Clinic during the years 1974 to 1976, a diagnosis of aseptic meningitis, meningoencephalitis, or encephalitis was entertained in 42 cases and an infectious agent was identified in 30 of them (Donat et al). The California virus was isolated in 19 cases and one of the enteroviruses (echovirus types 19, 16, 21, or Coxsackie virus) in 8 cases; mumps, rubella, HSV, adeno virus 3, and M. pneumoniae were detected in individual cases (several patients had combined infections). As mentioned, recent outbreaks of West Nile virus, close to 3000 cases yearly in the United States, make it more important than most of the viral infections listed here. The related Japanese encephalitis virus is even more ubiquitous on a worldwide basis, causing 10,000 deaths in Asia each year.

Arboviral Encephalitis

The common arthropod-borne viruses (arboviruses) that cause encephalitis in the United States and their geographic range have been listed earlier. There are alternating cycles of viral infection in mosquitoes and vertebrate hosts; the mosquito becomes infected by taking a blood meal from a viremic host (horse or bird) and injects virus into the host, including humans. The seasonal incidence of these infections is practically limited to the summer and early fall, when mosquitoes are biting. In the equine encephalitides, regional deaths in horses usually precede human epidemics. In St. Louis encephalitis, the urban bird or animal or possibly the human becomes the intermediate host. West Nile outbreaks are preceded by illness in common birds such as crows and jays. St. Louis, California and La Crosse agents are endemic in the United States because of the cycle of infection in small rodents.

The clinical manifestations of the various arbovirus infections are almost indistinguishable from one another, although they do vary with the age of the patient. The incubation period after mosquito bite transmission is 5 to 15 days. There may be a brief prodromal fever with arthralgias or rash (e.g., West Nile fever). In infants, there may be only an abrupt onset of fever and convulsions. In older children, the onset is usually less abrupt, with complaints of headache, listlessness, nausea or vomiting, drowsiness, and fever for several days before medical attention is sought; convulsions, confusion, stupor, and stiff neck then become prominent. Photophobia, diffuse myalgia, and tremor (of either action or intention type) may be observed in this age group and in adults. Asymmetry of tendon reflexes, hemiparesis, extensor plantar signs, myclonus, chorea, and sucking and grasping reflexes may also occur. McJunkin and colleagues have described the clinical features of 127 patients with La Crosse infection seen at their medical center over a decade, and their data are representative of other arboviral infections. In addition to the typical features of viral encephalitis, they emphasize, in a proportion of patients, hyponatremia, raised intracranial pressure with cerebral swelling, and, most notable to us, signal changes in the MRI that simulate herpes encephalitis. It affects children mainly, causing fever, seizures, and focal neurologic signs, but is otherwise benign in most instances, with full recovery. A special syndrome of febrile, flaccid, paralytic poliomyelitis resulting from West Nile virus infection has also been described. It evolves over several days and in a few cases is accompanied by facial paralysis (see Jeha et al). A few cases have begun with an extrapyramidal syndrome; these syndromes occur also with the other flaviviruses (Japanese encephalitis, Murray valley, St. Louis).
The CSF findings are much the same as in aseptic meningitis (lymphocytic pleocytosis, mild protein elevation, normal glucose values). Recovery of virus from blood or CSF is usually not possible and PCR testing has not been routinely applied. However, antiviral IgM is present within the first days of symptomatic disease and can be detected and quantified by means of ELISA. Some patients have not developed antibodies by the time of admission to the hospital and the test may have to be repeated. The MRI may be normal or show signal changes and edema in the cortex, basal ganglia, or thalamus (the latter is described in the Japanese virus group). The fever and neurologic signs subside after 4 to 14 days unless death supervenes or destructive CNS changes have occurred. No antiviral agents are known to be effective in the treatment of arboviral encephalitis; one must rely entirely on supportive measures; on occasion, brain swelling reaches a degree that requires specific therapy, as outlined on pages 317 and 766.

The pathologic changes consist of widespread degeneration of single nerve cells, with neuronophagia as well as scattered foci of inflammatory necrosis involving both the gray and white matter. The brainstem is relatively spared. In some cases of eastern equine encephalitis, the destructive lesions may be massive, involving the major part of a lobe or hemisphere and are readily displayed by MRI, but in the other arbovirus infections the foci are microscopic in size (see Deresiewicz et al). West Nile virus may also produce a regional pattern of neuronal damage that affects the anterior horn cells of the spinal cord, as mentioned above. A pathologic description of this process has been provided by our colleagues and by others (see Asnis et al). Perivascular cuffing by lymphocytes and other mononuclear leukocytes and plasma cells as well as a patchy infiltration of the meninges with similar cells are the usual histopathologic hallmarks of viral encephalitis.

Of the arbovirus infections in the United States, eastern equine encephalitis is among the most serious, since a large proportion of those infected develop encephalitis; about one-third die and a similar number, more often children, are left with disabling abnormalities—mental retardation, emotional disorders, recurrent seizures, blindness, deafness, hemiplegia, extrapyramidal motor abnormalities, and speech disorders. While only a small proportion of those exposed become infected, the poliomyelitis and parkinsonian syndromes of the flaviviruses may be permanent residua as of those infected. In the acute stages of arboviral encephalitis; one must rely entirely on supportive measures; on occasion, brain swelling reaches a degree that requires specific therapy, as outlined on pages 317 and 766.

**Herpes Simplex Encephalitis**

This is the commonest and gravest form of acute encephalitis. About 2000 cases occur yearly in the United States, accounting for about 10 percent of all cases of encephalitis in this country. Between 30 and 70 percent are fatal, and the majority of patients who survive are left with serious neurologic abnormalities. HSV encephalitis occurs sporadically throughout the year and in patients of all ages and in all parts of the world. It is due almost always to HSV-1, which is also the cause of the common herpetic lesions of the oral mucosa; rarely, however, are the oral and encephalitic lesions concurrent. The type 2 virus may also cause acute generalized encephalitis, usually in the neonate and in relation to genital herpetic infection in the mother. Type 2 infection in the adult may cause an aseptic meningitis and sometimes a polyradiculitis or myelitis, again in association with a recent genital herpes infection. Exceptionally, the localized adult type of encephalitis is caused by the type 2 virus and the diffuse neonatal encephalitis by type 1.

**Clinical Features** The symptoms, which evolve over several days, are in most cases like those of any other acute encephalitis—namely, fever, headache, seizures, confusion, stupor, and coma. In some patients these manifestations are preceded by symptoms and findings that betray the predilection of this disease for the inferomedial portions of the frontal and temporal lobes. They include olfactory or gustatory hallucinations, anosmia, temporal lobe seizures, personality change, bizarre or psychotic behavior or delirium, aphasia, and hemiparesis. Although several seizures at the onset of illness are not an uncommon presentation, status epilepticus is rare. An affection of memory can often be recognized, but usually this becomes evident only later, in the convalescent stage, as the patient awakens from stupor or coma. Swelling and herniation of one or both temporal lobes through the tentorium may occur, leading to deep coma and respiratory arrest during the first few days of the illness.

The CSF is typically under increased pressure and almost invariably shows a pleocytosis (range, 10 to 200 cells per cubic millimeter, infrequently more than 500). The cells are mostly lymphocytes, but there may be a significant number of neutrophils early on. In a few cases, 3 to 5 percent in some large series, the spinal fluid has been normal in the first days of the illness, only to become abnormal when re-examined. Also, in only a minority of cases, red cells, sometimes numbering in the thousands, and xanthochromia are found, reflecting the hemorrhagic nature of the brain lesions; but it should be emphasized that more often red cells are few in number or absent. The protein content is increased in most cases. Rarely, the CSF glucose levels may be reduced to slightly less than 40 mg/dL, creating confusion with tuberculous and fungal meningitides.

**Pathology** The lesions take the form of an intense hemorrhagic necrosis of the inferior and medial temporal lobes and the mediobasal parts of the frontal lobes. The region of necrosis may extend upward along the cingulate gyri and sometimes to the insula or the lateral parts of the temporal lobes or caudally into the midbrain but always contiguous with areas of mediotemporal lobe necrosis. The temporal lobe lesions are usually bilateral but not symmetrical. This distribution of lesions is so characteristic that the diagnosis can be made by gross inspection or by their location and appearance on imaging studies. Cases described in past years as “acute necrotizing encephalitis” and “inclusion body encephalitis” were likely to have been instances of HSV encephalitis. In the acute stages of the disease, intranuclear eosinophilic inclusions are found in neurons and glial cells, in addition to the usual microscopic abnormalities of acute encephalitis and hemorrhagic necrosis.

The unique localization of the lesions in this disease could possibly be explained by the virus’s route of entry into the CNS. Two such routes have been suggested (Davis and Johnson). The virus is thought to be latent in the trigeminal ganglia and, with reactivation, to infect the nose and then the olfactory tract. Alternatively, with reactivation in the trigeminal ganglia, the infection may spread along nerve fibers that innervate the leptomeninges of the anterior and middle fossae. The lack of lesions in the olfactory bulbs in as many as 40 percent of fatal cases (Esiri) is a point in favor of the second pathway.

**Diagnosis** Acute herpes simplex encephalitis must be distinguished from other types of viral encephalitis, from acute hemorrhagic leukoencephalitis of Weston Hurst (page 792), and from subdural empyema, cerebral abscess, cerebral venous thrombosis, and septic embolism (Chap. 32). When aphasia is the initial man-
manifestation of the illness, it may be mistaken for a stroke. The CSF findings have been mentioned and are typical of a meningoencephalitis. Spinal fluid that contains a large number of red cells may be attributed to a ruptured saccular aneurysm. The electroencephalographic (EEG) changes, consisting of lateralized periodic high-voltage sharp waves in the temporal regions and slow-wave complexes at regular two- to three-per-second intervals, are highly suggestive in the appropriate clinical context, though they are not specific for the disease.

CT scans show hypodensity of the affected areas in 50 to 60 percent of cases and MRI shows signal changes in almost all (increased signal in T2-weighted images; Fig. 33-1). T1-weighted images demonstrate areas of low signal intensity with surrounding edema and sometimes with scattered areas of hemorrhage occupying the inferior parts of the frontal and temporal lobes. Almost always the lesions enhance with contrast infusion or with gadolinium, indicating cortical and pial abnormalities of the blood-brain barrier. It should be noted that these destructive lesions are almost unique among the viral encephalitides, being seen only occasionally in other viral infections of the brain, among them La Crosse encephalitis in children (McJunkin et al).

A rising titer of neutralizing antibodies can be demonstrated from the acute to the convalescent stage, but this is not of diagnostic help in the acutely ill patient and may not be significant in patients with recurrent herpes infections of the oral mucosa. More recently, tests for the detection of HSV antigen in the CSF by the application of PCR have been developed and are useful in diagnosis while the virus is replicating in the first few days of the illness (Rowley et al). A refinement in this technique (a nested PCR assay), described by Aurelius and coworkers, reportedly has a sensitivity of 95 percent and gives virtually no false-positive tests in the first 3 weeks of illness. In the experience of Lakeman and colleagues, the test was 98 percent positive in cases proven by cultures of brain biopsy material and gave 6 percent false-positives. Antiviral treatment did not appear to affect the test. False-negative tests are most likely to occur in the first 48 h of febrile infection. The only alternative way to establish the diagnosis of acute HSV encephalitis is by fluorescent antibody study and by viral culture of cerebral tissue obtained by brain biopsy; the approach to biopsy as a diagnostic test varies among centers but its use has declined with the availability of the PCR test. We find it necessary to perform biopsy in only a minority of cases, preferring to treat the patient with antiviral agents based on compatible clinical, radiologic, and CSF findings while we await serologic and PCR test results.

**Treatment** Until the late 1970s, there was no specific treatment for HSV encephalitis. A collaborative study sponsored by the National Institutes of Health and also a Swedish study indicated that the antiviral agent acyclovir significantly reduces both mortality and morbidity from the disease (Whitley et al; Sköldenberg et al). For this reason, it is our practice to initiate treatment while confirmatory testing is being carried out. Acyclovir is given intravenously in a dosage of 30 mg/kg per day and continued for 10 to 14 days in order to prevent relapse. Acyclovir carries little risk and can be discontinued if further clinical or laboratory features point to another diagnosis. The main problems that arise from the drug are local irritation of the veins used for infusion, mild elevation of hepatic enzymes, or transient impairment of renal function. Nausea, vomiting, tremor, or an encephalopathy that is difficult to distinguish from the encephalitis itself occur in a very few patients.

The matter of relapse after treatment with acyclovir has been recognized increasingly, particularly in children. Several potential mechanisms have been suggested by Tiège and colleagues, including an immune-mediated inflammatory response, but treatment with too low a dose or for too brief a period is undoubtedly the main cause of the rare relapses that occur in adults. In children, a second course of acyclovir is usually successful.

When a large volume of brain tissue is involved, the hemorrhagic necrosis and surrounding edema act as an enlarging mass that requires separate attention. Coma and pupillary changes should

---

**Figure 33-1.** Herpes simplex encephalitis. *Left:* a T2-weighted coronal MRI in the axial plane, taken during the acute stage of the illness. There is increased signal from practically all of the inferior and deep temporal lobe and the insular cortex. *Right:* a T1-weighted image after gadolinium infusion showing enhancement of the left insular and temporal cortices and early involvement of the right temporal lobe.
not be attributed to the mass effect unless compression of the upper brainstem is evident on brain imaging, since the infection is capable of spreading to the mesencephalon from the contiguous deep temporal lobe, thereby causing coma by a direct destructive effect. All measures used in the management of brain edema due to mass lesions should be applied, but there are insufficient data by which to judge their effectiveness. The concern that corticosteroids may aggravate the infection has not been borne out by clinical experience, but a detrimental effect cannot be discounted. Our experience (reported by Barnett et al) and that of Schwab and colleagues has been that the presence of raised intracranial pressure early in the illness presages a poor outcome. Seizures are usually brought under control by high doses of conventional anticonvulsants.

The outcome of this disease, both the mortality and morbidity, is governed to a large extent by the patient’s age and state of consciousness at the time of institution of acyclovir therapy. If the patient is unconscious (except immediately after a convulsion), the outcome is uniformly poor. However, if treatment is begun within 4 days of onset of the illness in an awake patient, survival is greater than 90 percent (Whitley). Evaluation of these patients 2 years after treatment showed 38 percent to be normal or nearly normal, whereas 53 percent were dead or severely impaired. The neurologic sequelae are often of the most serious type, consisting of a Kirkhoff amnesic defect or a global dementia, seizures, and aphasia (Drachman and Adams). If there were seizures during the acute illness, it is advisable to continue anticonvulsants for a year or more and then judge the advisability of discontinuing them on the basis of further seizures, the EEG, and the patient’s exposure to situations that pose a danger, such as driving. With the exception of the aforementioned rare relapsing cases, the infection does not recur.

**Rabies**

This disease also stands apart from other acute viral infections by virtue of the latent period that follows inoculation with the virus and its distinctive clinical and pathologic features. Human examples of this disease are rare in the United States; between 1980 and 1997, only 34 such cases are known to have occurred; since 1960, there have never been more than 5 or so cases in any one year. In some areas (Australia, Hawaii, Great Britain, and the Scandinavian peninsula), no indigenous cases have ever been reported; in India, however, there is a high incidence. The importance of this disease derives from two facts: it has been almost invariably fatal once the characteristic clinical features appear; hence the survival of the infected individual depends upon the institution of specific therapeutic measures before the infection becomes clinically evident. Furthermore, each year 20,000 to 30,000 individuals are treated with rabies vaccine, having been bitten by animals that possibly were rabid, and although the incidence of complications with the newer rabies vaccination is much lower than before, a few serious reactions continue to be encountered (see below and also Chap. 36).

**Etiology**

Practically all cases of rabies are the result of transdermal viral inoculation by an animal bite. In undeveloped countries, where rabies is relatively common, the most frequent source is the rabid dog. In western Europe and the United States, the most common rabid species are raccoons, skunks, foxes, and bats among wild animals and dogs and cats among domestic ones. Because rabid animals commonly bite without provocation, the nature of the attack should be determined. Also, the prevalence of animal rabies virus varies widely in the United States, and local presence of the disease is useful in assessing risk. As indicated in the introductory section, the virus spreads along peripheral nerves to reach the nervous system. Rare cases have been caused by inhalation of the virus shed by bats; in a few cases the source of the infection may not be identifiable. The epidemiology and public health aspects of rabies have been reviewed by Fishbein and Robinson.

**Clinical Features**

The incubation period is usually 20 to 60 days but may be as short as 14 days, especially in cases involving multiple deep bites around the face and neck. Tingling or numbness at the site of the bite, even after the wound has healed, is characteristic. This is thought to reflect an inflammatory response that is incited when the virus reaches the sensory ganglia. The main neurologic symptoms (following a 2- to 4-day prodromal period of fever, headache, and malaise) consist of severe apprehension, dysarthria, and psychomotor overactivity, followed by dysphagia (hence salivation and “frothing at the mouth”), spasms of throat muscles induced by attempts to swallow water or in rare cases by the mere sight of water (hence “hydrophobia”), dysarthria, numbness of the face, and spasms of facial muscles. This localization indicates the involvement of the segmental medullary nuclei in the rabid form of the disease. Generalized seizures, confusional psychosis, and a state of agitation may follow. A less common paralytic form (“dumb” rabies of older writings, in distinction to the above described “furious” form) due to spinal cord infection, may accompany or replace the state of excitement. The paralytic form is most likely to follow bat bites or, in the past, the administration of rabies vaccination. Coma gradually follows the acute encephalitic symptoms and death ensues within 4 to 10 days, or longer in the paralytic form. With modern intensive care techniques, there have been a number of survivors. In addition to mechanical respiratory support, several secondary abnormalities must be addressed, including raised intracranial pressure, excessive release of antidiuretic hormone, diabetes insipidus, and extremes of autonomic dysfunction, especially hyper- and hypotension.

**Pathologic Features**

The disease is distinguished by the presence of cytoplasmic eosinophilic inclusions, the Negri bodies. They are most prominent in the pyramidal cells of the hippocampus and the Purkinje cells but have been seen in nerve cells throughout the CNS. In addition there may be widespread perivascular cuffing and meningeal infiltration with lymphocytes and mononuclear cells and small foci of inflammatory necrosis, such as those seen in other viral infections. The inflammatory reaction is most intense in the brainstem. The focal collections of microglia in this disease are referred to as Babes nodules (named for Victor Babes, a Romanian microbiologist).

**Treatment**

Bites and scratches from a potentially rabid animal should be thoroughly washed with soap and water and, after all soap has been removed, cleansed with benzyl ammonium chloride (Zephiran), which has been shown to inactivate the virus. Wounds that have broken the skin also require tetanus prophylaxis.

After a bite by a seemingly healthy animal, surveillance of the animal for a 10-day period is necessary. Should signs of illness appear in the animal, it should be killed and the brain sent, under refrigeration, to a government-designated laboratory for appropriate diagnostic tests. Wild animals, if captured, should be killed and the brain examined in the same way.

If the animal is found by fluorescent antibody or other tests to be rabid or if the patient was bitten by a wild animal that escaped,
postinfectious process (see Chap. 36), but the finding of frag-
cases have shown an inflammatory pathology most suggestive of
extensive pathologic study, there is still uncertainty regarding the

Acute Cerebellitis (Acute Ataxia of

A special comment should be made here concerning the dramatic
syndrome of acute ataxia that occurs in the context of an infectious
illness. The syndrome was originally described by Westphal in
1872 following smallpox and typhoid fever in adults, but Batten is
credited with drawing attention to the more common ataxic illness
that occurs after certain childhood infections such as measles, per-
tussis, and scarlet fever. Currently, acute ataxia of childhood is
most often associated with chickenpox (one-quarter of 73 consecu-
tive cases reported by Connolly et al), but it can occur during or
after any of the childhood exanthems, as well as in association with
infections due to enteroviruses (mainly Coxsackie), EBV, Myco-
plasma, CMV, Q fever, vaccinia, a number of vaccinations, rarely
with HSV, and also after nondescript respiratory infections (see
Weiss and Guberman). The condition is far less frequent in adults,
but we encounter a case every 2 years or so in adolescents and
individuals in their twenties; besides a late case of varicella, the
most common preceding organisms in these individuals have been
EBV and Mycoplasma.

The syndrome, which is essentially a “meningocerebellitis,”
appears relatively abruptly, over a day or so, and consists of limb
and gait ataxia and often dysarthria and nystagmus. Additional
signs include increased limb tone, Babinski signs, or confusion.
The fever of the original infection may have abated, or it may

Syndromes of Herpes Zoster

Herpes zoster (“shingles,” “zona”) is a common viral infection of
the nervous system occurring at an overall rate of 3 to 5 cases per
1000 persons per year, with higher rates in the elderly. Shingles
is distinctly rare in childhood. It is characterized clinically by
radicular pain, a vesicular cutaneous eruption, and, less often, by
segmental sensory and delayed motor loss. The pathologic changes
consist of an acute inflammatory reaction in isolated spinal or cra-
nial sensory ganglia and lesser degrees of reaction in the posterior
and anterior roots, the posterior gray matter of the spinal cord, and
the adjacent leptomeninges.

The neurologic implications of the segmental distribution of
the rash were recognized by Richard Bright as long ago as 1831.
Inflammatory changes in the corresponding ganglia and related por-
tions of the spinal nerves were first described by von Baren sprung
in 1862 and were later studied extensively. The concept that vari-
cella and zoster are caused by the same agent was introduced by
von Bokay in 1909 and was subsequently established by Weller
and his associates (1954, 1958). The common agent, referred to as
varicella or varicella zoster virus (VZV), is a DNA virus that is
similar in structure to the virus of herpes simplex. These and other
historical features of herpes zoster have been reviewed by Denny-
Brown and Adams and by Weller and their colleagues.

Pathology and Pathogenesis The pathologic changes in VZV
infection are unique and consist of one or more of the following:
(1) an inflammatory reaction in several unilateral adjacent sensory
ganglia of the spinal or cranial nerves, frequently of such intensity
as to cause necrosis of all or part of the ganglion, with or without
hemorrhage; (2) an inflammatory reaction in the spinal roots and
peripheral nerve contiguous with the involved ganglia; (3) a less
common polyneuropathy that closely resembles acute anterior poli-
omyelitis but is readily distinguished by its unilaterality, segmental
localization, and greater involvement of the dorsal horn, root, and
ganglion; and (4) a relatively mild leptomeningitis, largely limited
to the involved spinal or cranial segments and nerve roots. These
pathologic changes are the substratum of the neuralgic pains, the
pleocytosis, and the local palsies that may attend and follow the
VZV infection. There may also be a delayed cerebral vasculitis
(see further on).

As to pathogenesis, herpes zoster represents a spontaneous
reactivation of VZV infection, which becomes latent in the neurons
of sensory ganglia following a primary infection with chickenpox
(Hope-Simpson). This hypothesis is consistent with the differences
in the clinical manifestations of chickenpox and herpes zoster, even
though both are caused by the same virus. Chickenpox is highly
contagious by respiratory aerosol, has a well-marked seasonal in-
cidence (winter and spring), and tends to occur in epidemics. Zos-
ter, on the other hand, is not communicable (except to a person
who has not had chickenpox), occurs sporadically throughout the
year, and shows no increase in incidence during epidemics of
chickenpox. In patients with zoster, there is practically always a
past history of chickenpox. Such a history may be lacking in rare
instances of herpes zoster in infants, but in these cases there has
usually been prenatal maternal contact with VZV.

VZV DNA is localized primarily in trigeminal and thoracic
ganglion cells, corresponding to the dermatomes in which chick-
enpox lesions are maximal and that are most commonly involved
by VZV (Mahalingam et al). The supposition is that in both zoster
and varicella infections the virus makes its way from the cutaneous
vesicles along the sensory nerves to the ganglion, where it remains latent until activated, at which time it progresses down the axon to the skin. Multiplication of the virus in epidermal cells causes swelling, vacuolization, and lysis of cell boundaries, leading to the formation of vesicles and so-called Lipschutz inclusion bodies. Alternatively, the ganglia could be infected during the viremia of chickenpox, but then one would have to explain why only one or a few sensory ganglia become infected. Reactivation of virus is attributed to waning immunity, which would explain the increasing incidence of zoster with aging and with lymphomas, administration of immunosuppressive drugs, AIDS, and radiation therapy.

The subject of pathogenesis of herpes zoster has been reviewed by Gilden and colleagues, and in a monograph by Rentier who describes the molecular and immune investigations pertaining to VZV.

Clinical Features As indicated above, the incidence of herpes zoster rises with age. Hope-Simpson has estimated that if a cohort of 1000 people lived to 85 years of age, half would have had one attack of zoster and 10 would have had two attacks. The notion that one attack of zoster provides lifelong immunity is incorrect, although recurrent attacks are rare and most repeated herpetic eruptions are due to HSV. The sexes are equally affected, as is each side of the body. Herpes zoster occurs in up to 10 percent of patients with lymphoma and 25 percent of patients with Hodgkin disease—particularly in those who have undergone splenectomy or received radiotherapy. Conversely, about 5 percent of patients who present with herpes zoster are found to have a concurrent malignancy (about twice the number that would be expected), and the proportion appears to be even higher if more than two adjacent dermatomes are involved.

The vesicular eruption is usually preceded for several days by itching, tingling, or burning sensations in the involved dermatome(s), and sometimes by malaise and fever as well. Or there is severe localized or radicular pain that may be mistaken for pleurisy, appendicitis, cholecystitis, or, quite often, ruptured intervertebral disc, until the diagnosis is clarified by the appearance of vesicles (nearly always within 72 to 96 h). The rash consists of clusters of tense clear vesicles on an erythematous base, which become cloudy after a few days (due to accumulation of inflammatory cells) and dry, crusted, and scaly after 5 to 10 days. In a small number of patients, the vesicles are confluent and hemorrhagic, and healing is delayed for several weeks. In most cases pain and dysesthesia last for 1 to 4 weeks; but in the others (7 to 33 percent in different series) the pain persists for months or, in different forms, even for years and presents a difficult problem in management. Impairment of superficial sensation in the affected dermatome(s) is common, and segmental weakness and atrophy are added in about 5 percent of patients. In the majority of patients the rash and sensomotor signs are limited to the territory of a single dermatome, but in some, particularly those with cranial or limb involvement, two or more contiguous dermatomes are involved. Rarely (and usually in association with malignancy) the rash is generalized, like that of chickenpox, or altogether absent.

In half of the cases, the CSF shows a mild increase in cells, mainly lymphocytes, and a modest increase in protein content (although lumbar puncture is not required to establish the diagnosis). The diagnosis can be confirmed by direct immunofluorescence of a biopsied skin lesion, using antibody to VZV, or inferred by finding multinucleated giant cells in scrapings from the base of an early vesicle. The spinal fluid also contains antibodies to the virus or evidence of the organism by PCR testing in 35 percent of cases, according to a prospective study by Haanpää and colleagues.

Virtually any dermatome may be involved in zoster, but some regions are far more frequent than others. The thoracic dermatomes, particularly T5 to T10, are the most common sites, accounting for more than two-thirds of all cases, followed by the craniocervical regions. In the latter cases the disease tends to be more severe, with greater pain, more frequent meningeal signs, and involvement of the mucous membranes.

There are two rather characteristic cranial herpetic syndromes—ophthalmic herpes and so-called geniculate herpes. In ophthalmic herpes, which accounts for 10 to 15 percent of all cases of zoster, the pain and rash are in the distribution of the first division of the trigeminal nerve, and the pathologic changes are centered in the gasserian ganglion. The main hazard in this form of the disease is herpetic involvement of the cornea and conjunctiva, resulting in corneal anesthesia and residual scarring. Palsies of extracocular muscles, ptosis, and mydriasis are frequently associated, indicating that the third, fourth, and sixth cranial nerves are affected in addition to the gasserian ganglion.

A less common but also characteristic cranial nerve syndrome consists of a facial palsy in combination with a herpetic eruption of the external auditory meatus, sometimes with tinnitus, vertigo, and deafness. Ramsay Hunt (whose name has been attached to the syndrome) attributed this syndrome to herpes of the geniculate ganglion. Denny-Brown and Adams found the geniculate ganglion to be only slightly affected in a man who died 64 days after the onset of a so-called Ramsay Hunt syndrome (during which time the patient had recovered from the facial palsy); there was, however, inflammation of the facial nerve. Herpes zoster of the palate, pharynx, neck, and retroauricular region (herpes occipitocollaris) depends on herpetic infection of the upper cervical roots and the ganglia of the vagus and glossopharyngeal nerves. Herpes zoster in this distribution may also be associated with the Ramsay Hunt syndrome.

Encephalitis and cerebral angiitis are rare but well-described complications of cervicocranial zoster, as discussed below, and a restricted but destructive myelitis is a similarly rare but often quite serious complication of thoracic zoster. Devinsky and colleagues reported their findings in 13 patients with zoster myelitis (all of them immunocompromised) and reviewed the literature on this subject. The signs of spinal cord involvement appeared 5 to 21 days after the rash and then progressed for a similar period of time. Asymmetrical paraparesis and sensory loss, sphincteric disturbances, and, less often, a Brown-Séquard syndrome were the usual clinical manifestations. The CSF findings were more abnormal than in uncomplicated zoster (pleocytosis and raised protein) but otherwise similar. The pathologic changes, which take the form of a necrotizing inflammatory myelopathy and vasculitis, involve not just the dorsal horn but also the contiguous white matter, predominantly on the same side and at the same segment(s) as the affected dorsal roots, ganglia, and posterior horns. Early therapeutic intervention with acyclovir appeared to be beneficial. Our experience with the problem includes an elderly man who was not immunosuppressed; he remained with an almost complete transverse myelopathy. Another rare complication of zoster, taking the form of a subacute amytrophy of a portion of a limb, is probably linked to a restricted form of VZV myelitis.

Many of the writings on zoster encephalitis give the impression of a severe illness that occurs temporally remote from the attack of shingles in an immunosuppressed patient. Indeed, such
instances have been reported in patients with AIDS and may be concurrent with the small vessel vasculitis described below. However, our experience is more in keeping with that of Jemsek and colleagues and of Peterslund, who described a less severe form of encephalitis in patients with normal immune systems. Several of our patients, all elderly women, developed self-limited encephalitis during the latter stages of an attack of shingles. They were confused and drowsy, with low-grade fever but little meningismus, and a few had seizures. Recovery was complete and the MRI was normal, in distinction to the vasculitic syndromes described below. In some reported cases, VZV has been isolated from the CSF, and specific antibody to VZV membrane antigen (VAMA) has been a regular finding in the CSF and serum, though it is hardly needed for purposes of diagnosis. The differential diagnosis in these elderly patients also includes a drowsy-confusional state induced by narcotics given for the control of pain. Varicella cerebellitis, a post- or para-infectious condition, is discussed above.

The cerebral angiitis that occasionally complicates VZV infection is histologically similar to granulomatous angiitis (page 732). Typically, 2 to 10 weeks after the onset specifically of ophthalmic zoster, the patient develops an acute hemiparesis, hemianesthesia, aphasia, or other focal neurologic or retinal deficits associated with a mononuclear pleocytosis in the spinal fluid and elevated IgG indices in the CSF. CT or MRI scans demonstrate small, deep infarcts in the hemisphere ipsilateral to the trigeminal zoster infection. Angiograms show narrowing or occlusion of the internal carotid artery adjacent to the ganglia; but in some cases, vasculitis is more diffuse, even involving the contralateral hemisphere. Whether the angiitis results from direct spread of the viral infection via neighboring nerves as postulated by Linnemann and Alvira or represents an allergic reaction during convalescence from zoster has not been settled. VZV-like particles have been found in the vessel walls, suggesting a direct infection, and viral DNA has been extracted from affected vessels. Since the exact pathogenetic mechanism is uncertain, treatment with both intravenous acyclovir and corticosteroids may be justified. There are occasional instances of a cerebral vasculitis following dermatomal zoster on the trunk, as in one of Gilden’s reported cases.

An entirely different type of delayed vasculitis that affects small vessels with which we have no experience is being reported in patients with AIDS and other forms of immunosuppression. In this condition, weeks or months after one or more attacks of zoster, a subacute encephalitis ensues, including fever and focal signs. Some cases apparently arise without a rash, but viral DNA and antibodies to VZV are found in the CSF. The MRI shows multiple cortical and white matter lesions, the latter being smaller and less confluent than in progressive multifocal leukoencephalopathy. There is usually a mild pleocytosis. Almost all cases have ended fatally. The vasculitic and other neurologic complications of zoster have been reviewed by Gilden and colleagues.

Finally, it must be conceded that a facial palsy or pain in the distribution of a trigeminal or segmental nerve (usually lumbar or intercostal) due to herpetic ganglioneuritis, may occur very rarely without involvement of the skin (zoster sine herpete); lumbar disc herniation may be suspected. In a few such cases, an antibody response to VZV has been found (Mayo and Booss), and Dueland and associates have described an immunocompromised patient who developed a pathologically and virologically proved zoster infection in the absence of skin lesions. Similarly, Gilden and colleagues recovered VZV DNA from two otherwise healthy immunocompetent men who had experienced chronic radicular pain without a zoster rash. But practically no instances of Bell’s palsy, tic douloureux, and intercostal neuralgia are associated with serologic evidence of activation of VZV (Bell’s palsy has instead been associated with HSV, as indicated on page 1181).

**Treatment** During the acute stage, analgesics and drying and soothing lotions, such as calamine, help to blunt the pain. Nerve root blocks may provide very temporary relief. After the lesions have dried, the repeated application of capsaicin ointment (derived from hot peppers) may relieve the pain in some cases by inducing a cutaneous anesthesia. When applied too soon after the acute stage, capsaicin is highly irritating and should be used cautiously. Acyclovir (800 mg orally five times daily for 7 days) shortens the duration of acute pain and speeds the healing of vesicles, provided that treatment is begun within approximately 48 h (some authorities say 72 h) of the appearance of the rash (McKendrick et al). Famcyclovir (500 mg three times daily for 7 days) or the better absorbed valacyclovir (2 g orally four times daily) are alternatives. It should be noted that several studies have suggested that the duration of postherpetic neuralgia is reduced by treatment during the acute phase with famcyclovir or valacyclovir, but the incidence of this complication is not markedly affected and a similar effect of shortening the illness has not been shown for acyclovir (see below).

All patients with ophthalmic zoster should receive acyclovir orally; in addition, acyclovir applied topically to the eye, in either a 0.1% solution every hour or a 0.5% ointment four or five times a day, is recommended by some ophthalmologists. Patients who are immunocompromised or have disseminated zoster (lesions in more than three dermatomes) receive intravenous acyclovir for 10 days. There is now available from state health agencies a VZV immune globulin (VZIG) that shortens the course of the cutaneous disease and may protect against its dissemination in immunosuppressed patients. While it may reduce the incidence of postherpetic neuralgia (see Hugler et al), this is not its main purpose and it does not appear to prevent or ameliorate CNS complications.

**Postherpetic Neuralgia** This severely painful syndrome follows shingles in 5 to 10 percent of patients but occurs at almost three times that often among individuals over age 60. The possible effect of acute treatment on the severity of postherpetic neuralgia is mentioned above.

The management of postherpetic pain and dysesthesia can be a trying matter for both the patient and the physician. It is likely that incomplete interruption of nerves results in a hyperpathic state, in which every stimulus excites pain. In a number of controlled studies, amitriptyline proved to be an effective therapeutic measure. Initially, it is given in doses of approximately 50 mg at bedtime; if needed, the dosage can be increased gradually to 125 mg daily. The addition of carbamazepine, gabapentin, or valproate may further moderate the pain, particularly if it is of lancinating type. Capsaicin ointment can be applied to painful skin, as noted above. A saline of two aspirin tablets, crushed and mixed with cold cream or chloroform (15 mL) and spread on the painful skin, is reported to be successful in relieving the pain for several hours (King). The effect of nerve root blocks is not consistent but this procedure may afford temporary relief. It should be emphasized that postherpetic neuralgia eventually subsides even in the most severe and persistent cases, but the short-term use of narcotics is appropriate when the pain is severe. Until the pain subsides, the physician must exercise skill and patience in its medical management (see page 125) and avoid the temptation of subjecting the patient to one of the many
surgical measures that have been advocated for this disorder. Many patients with the most persistent complaints, beyond a year, have all the major symptoms of a depressive state and will be helped by appropriate antidepressive medications.

NEUROLOGIC DISEASES INDUCED BY RETROVIRUSES AND RESULTANT OPPORTUNISTIC INFECTIONS

Retroviruses are a large group of RNA viruses, so called because they contain the enzyme reverse transcriptase, which permits the reverse flow of genetic information from RNA to DNA. Two families of retroviruses are known to infect humans: (1) the lentiviruses, the most important of which is the human immunodeficiency virus (HIV), the cause of AIDS, and (2) the oncornaviruses, which include the human T-cell lymphotropic viruses, i.e., the agents that induce chronic T-cell leukemias and lymphomas (HTLV-II) and tropical spastic paraparesis (HTLV-I).

In the following pages, we consider the major neurologic syndromes induced by the two main human retroviruses—AIDS, a constellation of neurologic diseases caused by HIV, and tropical spastic paraparesis, caused by HTLV-I. These diseases are now the subjects of great public interest and laboratory investigation. A comprehensive account of the neurobiology, pathology, and clinical features of these infections can be found in the appropriate sections of Harrison’s Principles of Internal Medicine.

The Acquired Immunodeficiency Syndrome (AIDS)

In 1981, physicians became aware of the frequent occurrence of otherwise rare opportunistic infections and neoplasms—notably Pneumocystis carinii pneumonia and Kaposi sarcoma—in otherwise healthy young homosexual men. The study of these patients led to the recognition of a new viral disease, AIDS. In 1983, Montagnier and his colleagues isolated a retrovirus from a homosexual patient with lymphadenopathy and named it “lymphadenopathy-associated virus” (LAV). Shortly thereafter, Gallo and associates described a retrovirus in the blood of AIDS patients, which they called “human T-cell lymphotropic virus” (now HTLV-III). These two viruses, LAV and HTLV-III, were shown to be identical, and an international commission changed the name to human immunodeficiency virus (HIV)—sometimes referred to as HIV-1 to separate it from a similar virus (HIV-2) associated with AIDS predominantly in West Africa and elsewhere in persons of West African origin.

HIV infection is characterized by an acquired and usually profound depression of cell-mediated immunity, as manifest by cutaneous anergy, lymphopenia, reversal of the T-helper/T-suppressor cell ratio—more accurately, CD4+/CD8+ lymphocytes, as a result of reduction in CD4+ cells—and depressed in vitro lymphoproliferative response to various antigens and mitogens. It is this failure of immune function that explains the development of a wide range of opportunistic infections and unusual neoplasms. Virtually all organ systems are vulnerable, including all parts of the CNS, the peripheral nerves and roots, and muscle. Moreover, the nervous system is susceptible not only to diseases that are due to immunosuppression but also to the AIDS virus infection per se.

At the time of this writing it was estimated by the World Health Organization (WHO) that approximately 34 million adults were infected worldwide and that about 850,000 adults in the United States were seropositive for the virus. By all accounts, the incidence will continue to increase in the immediate future. Particularly startling are the statistics from sub-Saharan Africa and Southeast Asia, where the WHO estimated that about 25,000,000 adults, or almost 9 percent of the adult population, were infected. In some areas of East Africa, 30 percent of adults are infected with the virus.

In the United States, AIDS affects mainly homosexual and bisexual males (53 percent of all cases) and male and female drug users (30 percent). Somewhat less than 3 percent of patients at risk are hemophiliacs and others who receive infected blood or blood products, and the disease has occurred in infants born of mothers with AIDS. Moreover, this virus may be transmitted by asymptomatic and still immunologically competent mothers to their offspring. Spread of the disease by heterosexual contact accounts for about 5 percent of cases, but this number is gradually increasing, partly through the activities of intravenous drug users. (By contrast, an estimated 80 percent of African AIDS patients acquire their disease through heterosexual contact.)

Clinical Features Infection with HIV produces a spectrum of disorders, ranging from clinically invident seroconversion to widespread lymphadenopathy and other relatively benign systemic manifestations ranging from diarrhea, malaise, and weight loss (the so-called AIDS-related complex, or ARC) and to full-blown AIDS, which comprises the direct effects of the virus on all organ systems as well as the complicating effects of a multiplicity of parasitic, fungal, viral, and bacterial infections and a number of neoplasms (all of which require cell-mediated immunity for containment). Until the recent advent of multiple antiviral drug therapy, once the manifestations of AIDS had become established, one-half of the patients died by 1 year and most by 3 years. Clinically, neurologic abnormalities were noted in only about one-third of patients with AIDS, but at autopsy the nervous system is affected in nearly all of them. The infections and neoplastic lesions of the nervous system that complicate AIDS are listed in Table 33-2. Details of their pathology are to be found in the articles by Sharer and by Bell.

It has already been mentioned that HIV infection may present as an acute asymptomatic meningitis, with a mild lymphocytic pleocytosis and modest elevation of CSF protein. The acute illness may also take the form of a meningoencephalitis or even a myelopathy or neuropathy (see below). Most patients recover from the initial acute neurologic illnesses; the relationship to AIDS may pass unrecognized, since these illnesses are quite nonspecific clinically and may precede seroconversion. Once seroconversion has occurred, the patient becomes vulnerable to all the late complications of HIV infection. In adults, the interval between infection and the development of clinical AIDS ranges from several months to 15 years or even longer (the mean latency is 8 to 10 years and 1 year or less in infants). It is believed that practically all seropositive individuals will sooner or later develop AIDS, although new drugs are constantly lengthening the latent period.

AIDS Dementia Complex In the later stages of HIV infection, the commonest neurologic complication is a subacute or chronic HIV encephalitis presenting as a form of dementia; formerly it was called AIDS encephalopathy or encephalitis, but it is now generally referred to as the AIDS dementia complex, or ADC (Navia and Price). It has been estimated that only 3 percent of AIDS cases
Neurologic complications in patients infected with HIV

**Brain**
- Predominantly nonfocal
  - AIDS dementia complex (subacute/chronic HIV encephalitis)
  - Acute HIV-related encephalitis
  - Cytomegalovirus encephalitis
  - Varicella zoster virus encephalitis
  - Herpes simplex virus encephalitis
  - Metabolic encephalopathies

- Predominantly focal
  - Cerebral toxoplasmosis
  - Primary CNS lymphoma
  - Progressive multifocal leukoencephalopathy
  - Cryptococcosis
  - Brain abscess/tuberculoma
  - Neurosyphilis (meningovascular)

**Cerebrovascular disorders** — notably nonbacterial endocarditis, cerebral hemorrhages associated with thrombocytopenia, and vasculitis

**Spinal cord**
- Vacuolar myelopathy
- Herpes simplex or zoster myelitis

**Meninges**
- Aseptic meningitis (HIV)
- Cryptococcal meningitis
- Tuberculous meningitis
- Syphilitic meningitis
- Metastatic lymphomatous meningitis

**Peripheral nerve and root**
- Infectious
  - Herpes zoster
  - Cytomegalovirus lumbar polyradiculopathy, virus- or immune-related
  - Acute and chronic inflammatory HIV polyneuritis
  - Mononeuritis multiplex
  - Sensorimotor demyelinating polyneuropathy
  - Distal painful sensory polyneuritis
  - Diffuse infiltrative lymphocytic syndrome (DILS)

**Figure 33-2.** MRI of AIDS leukoencephalopathy. There are large areas of white matter change that underlie one form of AIDS dementia; cortical atrophy and ventricular enlargement are evident.

---

The pathologic basis of the dementia appears to be a diffuse and multifocal rarefaction of the cerebral white matter, accompanied by scanty perivascular infiltrates of lymphocytes and clusters of a few foamy macrophages, microglial nodules, and multinucleated giant cells (Navia et al). Evidence of CMV infection may be added, but accumulating virologic evidence indicates that the AIDS dementia complex is due to direct infection with HIV. Which of these changes, or the cortical atrophy, correspond most closely to the presence and severity of dementia has not been settled. The pathologic changes in AIDS dementia are actually not as uniform as portrayed here. In one group of patients, there is a diffuse pallor of the cerebral white matter, most obvious with myelin stains, accompanied by reactive astrocytes and macrophages; the myelin pallor seems to reflect a breakdown of the blood-brain barrier. In another form of this process, referred to as “diffuse poliodystrophy,” there is widespread astrocytosis and microglial activation in the

binksi signs, grasp and suck reflexes, weakness of the legs progressing to paraplegia, bladder and bowel incontinence reflecting spinal cord or cerebral involvement, and abulia or mutism are prominent in the later stages of the disease. In the untreated case, the dementia evolves relatively rapidly, over a period of weeks or months; survival after the onset of dementia is generally 3 to 6 months but may be considerably longer. Tests of psychomotor speed seem to be most sensitive in the early stages of dementia (e.g., trail-making, pegboard, and symbol-digit testing).

Epstein and colleagues have described a similar disorder in children, who develop a progressive encephalopathy as the primary manifestation of AIDS. The disease in children is characterized by an impairment of cognitive functions and spastic weakness and secondarily by impairment of brain growth.

The CSF in patients with AIDS dementia (but lacking other manifestations of AIDS) may be normal or show only a slight elevation of protein content and, less frequently, a mild lymphocytosis. HIV can be isolated from the CSF. In the CT scan there is widening of the sulci and enlargement of the ventricles; MRI may show patchy but confluent or diffuse white matter changes with ill-defined margins (Fig. 33-2). These findings are particularly useful in diagnosis, although CMV infection of the brain in AIDS patients produces a similar MRI appearance, as described further on.

The pathologic basis of the dementia appears to be a diffuse and multifocal rarefaction of the cerebral white matter, accompanied by scanty perivascular infiltrates of lymphocytes and clusters of a few foamy macrophages, microglial nodules, and multinucleated giant cells (Navia et al). Evidence of CMV infection may be added, but accumulating virologic evidence indicates that the AIDS dementia complex is due to direct infection with HIV. Which of these changes, or the cortical atrophy, correspond most closely to the presence and severity of dementia has not been settled. The pathologic changes in AIDS dementia are actually not as uniform as portrayed here. In one group of patients, there is a diffuse pallor of the cerebral white matter, most obvious with myelin stains, accompanied by reactive astrocytes and macrophages; the myelin pallor seems to reflect a breakdown of the blood-brain barrier. In another form of this process, referred to as “diffuse poliodystrophy,” there is widespread astrocytosis and microglial activation in the

cerebral cortex, with little recognizable neuronal loss. In other patients, small or large perivascular foci of demyelination, like those of postinfectious encephalomyelitis, are observed; the nature of this diffuse lesion is not understood. These forms of pathologic change may occur singly or together and all correlate poorly with the severity of the dementia.

AIDS Myelopathy, Peripheral Neuropathy, and Myopathy A myelopathy, taking the form of a vacuolar degeneration that bears a striking resemblance to subacute combined degeneration due to vitamin $B_12$ deficiency, is sometimes associated with the AIDS dementia complex; or the myelopathy may occur in isolation, as the leading manifestation of the disease (Petito et al.). This disorder of the spinal cord is discussed further on page 1059.

AIDS may also be complicated by several forms of peripheral neuropathy. Of 50 such patients reported by Snider and coworkers, 8 had a distal, symmetrical, axonal polyneuropathy, predominantly sensory and dysesthetic in type. This has been the most common neuropathic pattern. The HIV virus has been isolated from the peripheral nerves and ganglia. In fact, this stands as the first proven sensory and dysesthetic in type. This has been the most common neuropathy leading manifestation of the disease (Petito et al.). This disorder of the spinal cord is discussed further on page 1059.

the total clinical picture is often uncertain. Despite this ambiguity, certain features have emerged as typical of CMV encephalitis in the AIDS patient. According to Holland and colleagues, late in the course of AIDS and usually concurrent with CMV retinitis, the encephalopathy evolves over 3 to 4 weeks. Its clinical features include an acute confusional state or delirium combined, in a small proportion of cases, with cranial nerve signs including ophthalmoplegia, nystagmus, ptosis, facial nerve palsy, or deafness. In one of our patients, there were progressive oculomotor palsy that began with light-fixed pupils. Pathologic specimens and MRI show the process to be concentrated in the ventricular borders, especially evident as T2 signal hyperintensity in these regions. It may be seen to extend more diffusely through the adjacent white matter and be accompanied by meningeal enhancement by gadolinium in a few cases. Extensive destructive lesions have also been reported; this has been true in two of our own cases. Such lesions may be associated with hemorrhagic changes in the CSF in addition to showing an inflammatory response. CMV may also produce a painful lumbar sacral polyradiculitis in AIDS.

The diagnosis of CMV infection during life is often difficult. Cultures of the CSF are usually negative and IgG antibody titers are nonspecifically elevated. Newer PCR methods may prove useful here. Where the diagnosis is strongly suspected, treatment with the antiviral agents ganciclovir and foscarinet has been recommended; but, as pointed out by Kalayjian and colleagues, the CMV disease may develop and progress while patients are taking these medications as a form of maintenance therapy.

Cryptococcal Infection Meningitis with this organism and less often solitary cryptococcoma are the most frequent fungal complications of HIV infection. Flagrant symptoms of meningitis or meningoencephalitis may be lacking, however, and the CSF may show little abnormality with respect to cells, protein, and glucose. For these reasons, evidence of cryptococcal infection of the spinal fluid should be actively sought with India ink preparations, antigen testing, and fungal cultures. Treatment is along the lines outlined (on page 621).

Varicella Zoster Cerebral infections with this virus are less common complications of AIDS, but when they do occur, they tend to be severe. They take the form of multifocal lesions of the cerebral white matter, somewhat like those of progressive multifocal leukoencephalopathy, a cerebral vasculitis with hemiplegia (usually in association with ophthalmic zoster), or rarely a myelitis. Encephalitis due to HSV-1 and HSV-2 has also been identified in the brains of AIDS patients, but the clinical correlates are unclear. There is no evidence that acyclovir or other antiviral agents are effective in any of these viral infections. Shingles involving several contiguous dermatomes is known to occur in AIDS, as in other immunosuppressed conditions.

Tuberculosis Two particular types of mycobacterial infection tend to complicate AIDS—Mycobacterium tuberculosis and Mycobacterium avium-intracellulare. Tuberculosis predominates among drug abusers and AIDS patients in underdeveloped countries, and a higher than usual proportion of these immunosuppressed individuals develop tuberculous meningitis. Diagnosis and treatment are along the same lines as in non-AIDS patients (page 612). Atypical mycobacterial infections are usually associated with other destructive cerebral lesions and respond poorly to therapy.

Neurosyphilis Syphilitic meningitis and meningovascular syphilis appear to have an increased incidence in AIDS patients. Cell counts in the CSF are unreliable as signs of luetic activity; diagnosis depends entirely upon serologic tests. It seems unlikely that AIDS causes false-positive tests for syphilis, but this remains to be settled.

Other rare organisms, such as Rochalimaea henselae (formerly Bartonella), the cause of cat-scratch fever, are found with unexpectedly high frequencies in AIDS patients and have been implicated in an encephalopathy. Progressive multifocal leukoencephalopathy, a viral disease now closely linked with the immunosuppressed state of AIDS, is discussed further on in this chapter.

Diagnostic Tests for HIV Infection Many screening tests are now available for the detection of antibodies to HIV. Most of them are based on an enzyme-linked immunosassay (ELISA or EIA), which has proved to be highly sensitive. However, there is a small incidence of false-positive reactions, particularly when these tests are used to screen persons at low risk for HIV infection. All positive EIA tests should therefore be repeated.

The Western blot test, which identifies antibodies to specific viral proteins, is more specific than EIA tests and is used to confirm a positive screening test. Indeterminate Western blot tests should be repeated monthly for several months to detect a rising concentration of antibodies. Newer tests, using purified antigens, are being developed and should be more specific than those currently available.

Treatment The treatment of HIV infection/AIDS, as is true for any chronic, life-threatening disease, is difficult. Patients and their families require counseling and education, and frequently psychologic support in addition to complex drug regimens. Drug therapy for HIV infection continues to change rapidly. A combination of three and sometimes four drugs, including the reverse transcriptase inhibitors (AZT and 3-TC or lamivudine, which act synergistically and cross the blood-brain barrier) and the newer protease inhibitors (such as indinavir) render 90 percent of patients free of detectable virus for over a year. It is believed that this approach will prolong survival, but it might be expected also to increase the prevalence of neurologic complications of AIDS, each of which needs to be treated as it is recognized. Referral to a specialist or a center devoted to the management of this disease may be required.

Tropical Spastic Paraparesis, HTLV-I Infection

Tropical spastic paraparesis (TSP) is an endemic neurologic disorder in many tropical and subtropical countries. Its cause was overlooked until 1985, when Gessain and coworkers found IgG antibodies to human T-lymphotropic virus type I (HTLV-I) in the sera of 68 percent of TSP patients in Martinique. The same antibodies were then identified in the CSF of Jamaican and Colombian patients with TSP and in patients with a similar neurologic disorder in the temperate zones of southern Japan. The latter disorder was originally called HTLV-I–associated myelopathy (HAM), but it is now considered to be identical to HTLV-I–positive TSP (Roman and Osame). It is a curious feature of this disorder that only a small proportion of HTLV-I–infected persons (estimated at 2 percent) develop a myelopathy. Sporadic instances have now been reported from many parts of the western world. It is transmitted in one of several ways—from mother to child, either across the placenta or
in breast milk; by intravenous drug use or blood transfusions; or by sexual contact. The age of onset is in mid–adult life, and it is more common in females than in males, in a ratio of 3:1.

The clinical and pathologic features of the disease are described in Chap. 44, on spinal cord disorders, and in several recommended reviews (Rodgers-Johnson et al); the differentiation from the progressive spinal form of multiple sclerosis, with which it is most likely to be confused, is discussed on page 785. There are also clinical and pathologic differences from the myelopathy caused directly by HIV infection. No form of treatment has proved effective in reversing this disorder, although there are anecdotal reports that the intravenous administration of immune globulin may halt its progress.

The retrovirus HTLV-II is less common than HTLV-I but the two are virologically very similar. There is a high rate of infection with HTLV-II among drug users who are coinfected with HIV. A few cases of myelopathy have been reported in HTLV-II–infected patients, similar in all respects to HTLV-I–associated myelopathy (Lehky et al).

Viral Infections of the Developing Nervous System Viral infections of the fetus, notably rubella and CMV, and HSV infection of the newborn are important causes of CNS abnormalities. They are considered in Chap. 38, under “Developmental Diseases of Infancy and Childhood.”

SYNDROME OF ACUTE ANTERIOR POLIOMYELITIS

In the past, this syndrome was almost invariably the result of infection by one of the three types of poliovirus. However, illnesses that clinically resemble poliovirus infections can be caused by other enteroviruses, such as Coxsackie viruses groups A and B and Japanese encephalitis virus as well as by West Nile virus. Epidemics of hemorrhagic conjunctivitis (due to enterovirus 70 and formerly common in Asia and Africa) are also, in a small percentage of cases, associated with a lower motor neuron paralysis resembling poliomyelitis (Wadia et al). In countries with successful poliomyelitis vaccination programs, these viruses are now the most common causes of the anterior poliomyelitis syndrome, as discussed further on. In some cases, the illnesses induced by these viruses are generally benign and the associated paralysis is in significant. West Nile virus may be an exception in that several instances of encephalitis have been associated with a severe asymmetrical flaccid poliomyelitis.

Of course, the important (paralytic) disease in this category is poliomyelitis. Although no longer a scourge in areas where vaccination is practiced, its lethal and crippling effects are still fresh in the memory of physicians who practiced in the 1950s. In the summer of 1955, when New England experienced its last epidemic, 3950 cases of acute poliomyelitis were reported in Massachusetts alone, and 2771 of these were paralytic. The details of this epidemic, described by Pope and colleagues, are worth reviewing by any student of the disease. Now, only about 15 cases of paralytic poliomyelitis are reported annually in the United States—about equally divided between unvaccinated children and unvaccinated adults, the latter exposed to a recently vaccinated infant. Furthermore, the paralytic residua of previous epidemics can still be seen everywhere. In these cases, a delayed progression of muscle weakness may sometimes seem to appear many years after the acute paralytic illness—a condition termed postpolio syndrome (page 943). And, of course, acute poliomyelitis is still a frequent illness in regions of the world where vaccines are not available. For these reasons and also because it stands as a prototype of a neurotropic viral infection, the main features of the disease should be known to neurologists.

Etiology and Epidemiology The disease is caused by a small RNA virus that is a member of the enterovirus group of the picornavirus family. Three antigenically distinct types have been defined, and infection with one does not protect against the others. The disease has a worldwide distribution; the peak incidence of infection in the northern hemisphere was in the months of July through September.

Poliomyelitis is a highly communicable disease. The main reservoir of infection is the human intestinal tract (humans are the only known natural hosts), and the main route of infection is fecal–oral, i.e., hand to mouth, as with other enteric pathogens. The virus multiplies in the pharynx and intestinal tract. During the incubation period, which is from 1 to 3 weeks, the virus can be recovered from both of these sites. In only a small fraction of infected patients is the nervous system invaded. Between 95 and 99 percent of infected patients are asymptomatic or experience only a nonspecific illness. It is the latter type of patient—the carrier with inapparent infection—who is most important in the spread of the virus from one person to another.

Clinical Manifestations The large majority of infections are inapparent, or there may be only mild systemic symptoms with pharyngitis or gastroenteritis (so-called minor illness or abortive poliomyelitis). The mild symptoms of poliomyelitis correspond to the period of viremia and dissemination of the virus; they give rise in most cases to an effective immune response—a feature that accounts for the failure to cause meningitis or poliomyelitis. In the relatively small proportion of patients in whom the nervous system is invaded, the illness still has a wide range of severity, from a mild attack of aseptic meningitis (nonparalytic or preparalytic poliomyelitis) to the most severe forms of paralytic poliomyelitis.

Nonparalytic or Preparalytic Poliomyelitis The prodromal symptoms consist of listlessness, generalized, nonthrobhbing headache, fever of 38 to 40°C (100.4 to 104°F), stiffness and aching in the muscles, sore throat in the absence of upper respiratory infection, anorexia, nausea, and vomiting. The symptoms may subside to a varying extent, to be followed after 3 to 4 days by recrudescence of headache and fever and by symptoms of nervous system involvement; more often the second phase of the illness blends with the first. Tenderness in the muscles, tightness of the hambstrings (spasm), and pain in the neck and back become increasingly prominent. Other early manifestations of nervous system involvement include irritability, restlessness, and emotional instability; these are frequently a prelude to paralysis. Added to these symptoms are stiffness of the neck on forward flexion and the characteristic CSF findings of aseptic meningitis. These symptoms may constitute the entire illness; alternatively, the preparalytic symptoms may be followed by paralytic ones.

Paralytic Poliomyelitis The weakness becomes manifest while the fever is at its height, or, just as frequently, as the temperature falls and the general clinical picture seems to be improving. Muscle weakness may develop rapidly, attaining its maximum severity in 48 h or even less; or it may develop more slowly or in stuttering fashion, over a week, rarely even longer. As a general rule, there is no progression of weakness after the temperature has been nor-
mal for 48 h. The distribution of spinal paralysis is quite variable; rarely there may be an acute symmetrical paralysis of the muscles of the trunk and limbs as occurs in the Guillain-Barré syndrome. Excessive physical activity and local injections during the period of asymptomatic infection were thought to favor the development of paralysis of the exercised muscles or injected limbs.

Coarse fasciculations are seen frequently as the muscles weaken; they are transient as a rule, but occasionally they persist. Tendon reflexes are diminished and lost as the weakness evolves and paralyzed muscles become flaccid. Patients frequently complain of paresthesias in the affected limbs, but objective sensory loss is seldom demonstrable. Retention of urine is a common occurrence during the early phase in adult patients, but it does not persist. Atrophy of muscle can be detected within 3 weeks of onset of paralysis, is maximal at 12 to 15 weeks, and is permanent.

Bulbar paralysis is more common in young adults, but usually such patients have spinal involvement as well. The most frequently involved cranial muscles are those of deglutition, reflecting involvement of the nucleus ambiguus. The other great hazards of bulbar disease are disturbances of respiration and vasomotor control—hiccough, shallowness and progressive slowing of respiration, cyanosis, restlessness and anxiety (air hunger), hypertension, and ultimately hypotension and circulatory collapse. When these disturbances are added to paralysis of diaphragmatic and intercostal musculature, the patient’s survival is threatened and the institution of respiratory assistance and intensive care becomes urgent.

Pathologic Changes and Clinicopathologic Correlations In fatal infections, lesions are found in the precentral (motor) gyrus of the brain (usually of insufficient severity to cause symptoms), brainstem, and spinal cord. The brunt of the disease is borne by the hypothalamus, thalamus, motor nuclei of the brainstem and surrounding reticular formation, vestibular nuclei and roof nuclei of the cerebellum, and mainly, giving the illness its name, the neurons of the anterior and intermediate gray matter of the spinal cord. In these areas, nerve cells are destroyed and phagocytosed by microgliocytes (neuropathia). A leukocytic reaction is present for only a few days, but mononuclear cells persist as perivascular accumulations for many months. Nuclear or cytoplasmic inclusion bodies are not seen. The earliest histopathologic changes are central chromatolysis of the nerve cells, along with an inflammatory reaction. These changes correlate with a multiplication of virus in the CNS and, in the infected monkey, precede the onset of paralysis by one or several days.

In Bodian’s experimental material, the infected motor neurons continued to function until a stage of severe chromatolysis was reached. Moreover, if damage to the cell had attained only the stage of central chromatolysis, complete morphologic recovery could be expected—a process that took a month or longer. After this time, the degrees of paralysis and atrophy were closely correlated with the number of motor nerve cells that had been destroyed; where limbs remain atrophic and paralyzed, less than 10 percent of neurons survived in corresponding cord segments.

Lesions in the motor nuclei of the brainstem are associated with paralysis in corresponding muscles, but only if severe in degree. The disturbances of swallowing, respiration, and vasomotor control are related to neuronal lesions in the medullary reticular formation, centered in the region of the nucleus ambiguus.

Atrophic, areflexic paralysis of muscles of the trunk and limbs relates, of course, to destruction of neurons in the anterior and intermediate horns of the corresponding segments of the spinal cord gray matter. Stiffness and pain in the neck and back, attributed to “meningeal irritation,” are probably related to the mild inflammatory exudate in the meninges and to the generally mild lesions in the dorsal root ganglia and dorsal horns. Probably these lesions also account for the muscle pain and paresthesias in parts that later become paralyzed. Abnormalities of autonomic function are attributable to lesions of autonomic pathways in the reticular substance of the brainstem and in the lateral horn cells in the spinal cord.

It is of interest that poliovirus has been readily isolated from CNS tissue of fatal cases but can rarely be recovered from the CSF during clinical disease. This is in contrast to the closely related Coxsackie and echo picornaviruses, which have been isolated frequently from the CSF during the neurologic illness.

Treatment Patients in whom acute poliomyelitis is suspected require careful observation of swallowing function, vital capacity, pulse, and blood pressure in anticipation of respiratory and circulatory complications. With paralysis of limb muscles, foot boards, hand and arm splints, and knee and trochanter rolls prevent foot drop and other deformities. Frequent passive movement prevents contractures and ankylosis.

Respiratory failure, due to paralysis of the intercostal and diaphragmatic muscles or to depression of the respiratory centers in the brainstem, calls for the use of a positive-pressure respirator and, in most patients, for a tracheostomy as well. It was during the epidemics of the last midcentury that the use of Drinker’s “iron lung” attained widespread use. The management of the pulmonary and circulatory complications does not differ from their management in diseases such as myasthenia gravis and the Guillain-Barré syndrome and is best carried out in special respiratory or neurologic intensive care units.

The authors know of no systematic study of the potency of antiviral agents in this disease.

Prevention Prevention, of course, has proved to be the most significant aspect and one of the outstanding accomplishments of modern medicine. The cultivation of poliovirus in cultures of human embryonic tissues and monkey kidney cells—the achievement of Enders and associates—made possible the development of effective vaccines. The first of these was the injectable Salk vaccine, containing formalin-inactivated virulent strains of the three viral serotypes. This was followed by the Sabin vaccine, which consists of attenuated live virus, administered orally in two doses 8 weeks apart; boosters are required at 1 year of age and again before starting school. Since 1965, the reported annual incidence rate of poliomyelitis in the United States has been less than 0.01 per 100,000 (compared to a rate of 24 cases per 100,000 during the years 1951 to 1955). Very rarely, poliomyelitis may follow vaccination (0.02 to 0.04 cases per million doses). The only obstacle to complete prevention of the disease is inadequate utilization of the vaccine. Conceivably, with an increasing lack of immunity in underdeveloped nations, outbreaks of poliomyelitis could occur once again.

Prognosis Mortality from acute paralytic poliomyelitis is between 5 and 10 percent—higher in the elderly and very young. If the patient survives the acute stage, paralysis of respiration and deglutition usually recovers completely; in only a small fraction of such patients is chronic respirator care necessary. Many patients also recover completely from muscular weakness, and the most severely paralyzed improve to some extent. The return of muscle strength occurs mainly in the first 3 to 4 months and is probably
the result of morphologic restitution of partially damaged nerve cells. Branching of axons of intact motor cells with collateral reinnervation of muscle fibers of denervated motor units may also play a part. Slow recovery of slight degree may then continue for a year or more, the result of hypertrophy of undamaged muscle. The so-called postpolio syndrome is discussed on page 943.

**Nonpoliovirus Poliomyelitis**

As indicated earlier, a number of RNA viruses that cause mundane upper respiratory or enteric infections are now the main, although still rare, causes of a sporadic poliomyelitic syndrome. Fifty-two cases were recorded by the Centers for Disease Control and Prevention over a 4-year period. Most of these have been due to one of the echoviruses and a lesser number to Coxsackie enteroviruses, particularly strains 70 and 71. The former leave little residual paralysis, but the Coxsackie viruses, which have been studied in several outbreaks in the United States, Bulgaria, and Hungary, have been more variable in their effects. Enterovirus 70 causes acute hemorrhagic conjunctivitis in limited epidemics and is followed by a poliomyelitis in 1 of every 10,000 cases. European outbreaks of enterovirus 71, known in the United States as a cause of hand-foot-and-mouth disease and of aseptic meningitis, have resulted in poliovirus-type paralysis including fatal bulb cases (Chumakov et al). In a recent outbreak of enterovirus 71 in Taiwan, Huang et al described a brainstem encephalitis with myoclonus and cranial nerve involvement in a high proportion of the patients.

Our own experience with this form of poliomyelitis has been with four patients who were referred over the years for paralyzing illnesses initially thought to be Guillain-Barré syndrome (Gorson et al). In each case, the illness began with fever and active aseptic meningitis (50 to 150 lymphocytes per cubic millimeter in the CSF), followed by backache and widespread, relatively symmetrical paralysis, including the oropharyngeal muscles, except for two cases in which the weakness was asymmetrical and limited to the arms. There were no sensory changes. One patient had a concurrent encephalitic illness and died months later. The evolving electromyographic changes suggested that the paralysis was due to a loss of anterior horn cells rather than to a motor neuropathy or to a purely motor radiculopathy, but this distinction was not always certain. MRI was remarkable in showing distinct changes in the gray matter of the cord, mainly ventrally (Fig. 33-3). No virus could be isolated from the CSF and serologic tests in two patients failed to implicate any of the usual encephalitic RNA viruses, including poliovirus. The patients had been immunized against the poliomyelitis viruses. The tendency of West Nile virus to cause a poliomyelitis has already been mentioned.

**SUBACUTE AND CHRONIC VIRAL INFECTIONS SIMULATING DEGENERATIVE DISEASE**

The idea that viral infections may lead to chronic disease, especially of the nervous system, had been entertained since the 1920s, but only in relatively recent years was it firmly established. The following indirect and direct evidence supported this view: (1) the demonstration of a slowly progressive noninflammatory degeneration of nigral neurons long after an attack of encephalitis lethargica; (2) the finding of inclusion bodies in cases of subacute and chronic sclerosing encephalitis; (3) the discovery of chronic neurologic disease in sheep caused by a conventional RNA virus (visna)—it was in relation to this disease in sheep that Sigurdsson first used the term *slow infection* to describe the long incubation periods during which the animals appeared well; and (4) the demonstration by electron microscopy of viral particles in the lesions of multifocal leukoencephalopathy and, later, isolation of the virus from the lesions. The suggestion that the late onset of progressive weakness after poliomyelitis (“postpolio syndrome”) might represent a slow infection has never been verified. Claims have also been made by numerous groups for a viral causation of multiple sclerosis, amyotrophic lateral sclerosis, and other degenerative diseases, but the evidence is questionable.

The slow infections of the nervous system due to conventional viruses include subacute sclerosing panencephalitis (measles), progressive rubella panencephalitis, progressive multifocal leukoencephalopathy (JC virus), and visna in sheep. These slowly progressive diseases, except for progressive multifocal leukoencephalopathy (PML), are decidedly rare. They are caused by conventional viruses and are not to be confused with a group of chronic neurologic diseases that also are sometimes referred to as “slow infections” but are due instead to nonconventional transmissible agents, now called *prions*. These are accorded a separate section later in this chapter.

**Subacute Sclerosing Panencephalitis (SSPE)**

This disease was first described by Dawson in 1934 under the title “inclusion body encephalitis” and extensively studied by Van Bogaert, who renamed it *subacute sclerosing panencephalitis*. It is now recognized to be the result of chronic measles infection. Never a common disease, the condition occurred until recently at a rate of about one case per million children per year. With the introduction and widespread use of measles vaccine, it has practically disappeared in the United States. Along with the eradication of polio, this has been one of the important advances in preventative neuropediatrics.

Subacute sclerosing panencephalitis affects children and adolescents for the most part, rarely appearing beyond the age of 10 years. Typically there is a history of primary measles infection at a very early age, often before 2 years, followed by a 6- to 8-year asymptomatic period. The illness evolves in several stages. Initially there is a decline in proficiency at school, temper outbursts and other changes in personality, difficulty with language, and loss of interest in usual activities. These soon give way to a severe and progressive intellectual deterioration in association with focal or

*Figure 33-3. MRI of the cervical cord MRI in a patient with nonpoliovirus poliomyelitis and an asymmetrical, flaccid, bibrachial paralysis. There is T2 signal change in the anterior regions of the gray matter.*
generalized seizures, widespread myoclonus, ataxia, and sometimes visual disturbances due to progressive chorioretinitis. As the disease advances, rigidity, hyperactive reflexes, Babinski signs, progressive unresponsiveness, and signs of autonomic dysfunction appear. In the final stage the child lies insensate, virtually “decorticated.” The course is usually steadily progressive, death occurring within 1 to 3 years. In about 10 percent of cases the course is more prolonged, with one or more remissions. In a similar number the course is fulminant, leading to death within months of onset. Exceptionally, the disease occurs in young adults. In two reported cases in pregnant women, blurred vision and weakness of limbs developed before they became akinetic and mute, without a trace of myoclonus or cerebellar ataxia. Nevertheless, the progressive ataxic-myoclonic chronic dementia in a child is so typical that bedside diagnosis is usually possible.

The EEG shows a characteristic abnormality consisting of periodic (every 5 to 8 s) bursts of 2- to 3-per-second high-voltage waves, followed by a relatively flat pattern. The CSF contains few or no cells, but the protein is increased, particularly the gamma globulin fraction, and agarose gel electrophoresis discloses oligoclonal bands of IgG. These have been shown to represent measles virus–specific antibody (Mehta et al). Both the serum and CSF contain high concentrations of neutralizing antibody to measles (rubeola) virus, but the virus has been recovered from the brain tissue only with difficulty. The MRI changes begin in the subcortical white matter and spread to the periventricular region (Anlar et al).

Histologically the lesions involve the cerebral cortex and white matter of both hemispheres and the brainstem. The cerebellum is usually spared. Destruction of nerve cells, neuronophagia, and perivascular cuffing by lymphocytes and mononuclear cells indicate the viral nature of the infection. In the white matter there is degeneration of medullated fibers (myelin and axis cylinders), accompanied by perivascular cuffing with mononuclear cells and fibrous gliosis (hence the term sclerosing encephalitis). Eosinophilic inclusions, the histopathologic hallmark of the disease, are found in the cytoplasm and nuclei of neurons and glial cells. Virions, thought to be measles nucleocapsids, have been observed in the inclusion-bearing cells examined electron microscopically.

How a ubiquitous and transient viral infection in a seemingly normal young child allows the development, many years later, of a rare encephalitis is a matter of speculation. Sever believes that there is a delay in the development of immune responses during the initial infection and a later inadequate immune responses that are incapable of clearing the suppressed infection. An alternative hypothesis is that certain brain cells fail to synthesize a so-called M protein, which is essential for the assembly of the viral membrane, and that this limitation of host-cell capability is related to the extent of viral seeding of the brain during the initial infection (Hall et al).

The differential diagnosis includes the childhood and adolescent dementing diseases such as lipid storage diseases (Chap. 37) and Schilder demyelinating disease (page 782). In presumptive clinical cases of SSPE, the findings of periodic complexes in the EEG, elevated gamma globulin and oligoclonal bands in the CSF, and elevated measles antibody titers in the serum and CSF are sufficient to make the diagnosis.

No effective treatment is available. The administration of amantadine and inosiplex was found by some investigators to lead to improvement and prolonged survival but others could not corroborate these effects. The therapeutic value of intrathecal administration of alpha interferon is being investigated.

Subacute Measles Encephalitis with Immunosuppression
Whereas SSPE occurs in children who were previously normal, another rare type of measles encephalitis has been described, affecting both children and adults with defective cell-mediated immune responses (Wolinsky et al). In this type, measles or exposure to measles precedes the encephalitis by 1 to 6 months. Seizures (often epilepsy partialis continua), focal neurologic signs, stupor, and coma are the main features of the neurologic illness and lead to death within a few days to a few weeks. The CSF may be normal, and levels of measles antibodies do not increase. Aicardi and colleagues have isolated measles virus from the brain of such a patient. The lesions are similar to those of SSPE (eosinophilic inclusions in neurons and glia, with varying degrees of necrosis) except that inflammatory changes are lacking. In a sense this subacute measles encephalitis is an opportunistic infection of the brain in an immunoodeficient patient. The relatively short interval between exposure and onset of neurologic disease, the rapid course, and lack of antibodies distinguish this form of subacute measles encephalitis from both SSPE and postmeasles (postinfectious) encephalomyelitis (Chap. 36).

Progressive Rubella Panencephalitis
Generally the deficits associated with congenital rubella infection are nonprogressive at least after the second or third year of life. There are, however, descriptions of children with the congenital rubella syndrome in whom a progressive neurologic deterioration occurred after a stable period of 8 to 19 years (Townsend et al; Weil et al). In 1978, Wolinsky described 10 cases of this syndrome, a few of them apparently related to acquired rather than to congenital rubella. Since then, this late-appearing progressive syndrome seems to have disappeared, no new cases having been reported in the past 30 years.

The clinical syndrome has been quite uniform. On a background of the fixed stigmata of congenital rubella, there occurs a deterioration in behavior and school performance, often associated with seizures, and, soon thereafter, a progressive impairment of mental function (dementia). Clumsiness of gait is an early symptom, followed by a frank ataxia of gait and then of the limbs. Spasticity and other corticospinal tract signs, dysarthria, and dysphagia ensue. Pallor of the optic discs, ophthalmoplegia, spastic quadriplegia, and mutism mark the final phase of the illness. The CSF shows a mild increase of lymphocytes and elevation of protein and a marked increase in the proportion of gamma globulin (35 to 52 percent of the total protein), which assumes an oligoclonal pattern on agarose gel electrophoresis. The CSF and serum rubella-antibody titers are elevated.

Pathologic examination of the brain has shown a widespread, progressive subacute panencephalitis mainly affecting the white matter. No inclusion-bearing cells were seen. Thus it appears that rubella virus infection, acquired in utero or in the postnatal period, may persist in the nervous system for years before rekindling a chronic active infection.

Progressive Multifocal Leukoencephalopathy (PML)
This disorder, first observed clinically by Adams and colleagues in 1952, was described morphologically by Åstrom and coworkers (1958) and then with a larger material by Richardson. It is characterized by widespread demyelinating lesions, mainly of the cerebral hemispheres but sometimes of the brainstem and cerebellum and rarely of the spinal cord. The lesions vary greatly in size and severity—from microscopic foci of demyelination to massive multifocal zones of destruction of both myelin and axis cylinders involving
the major part of a cerebral or cerebellar hemisphere (Fig. 33-4). The abnormalities of the glial cells are distinctive. Many of the reactive astrocytes in the lesions are gigantic and contain deformed and bizarre-shaped nuclei and mitotic figures, changes that are seen otherwise only in malignant glial tumors. Also, at the periphery of the lesions, the nuclei of oligodendrocytes are greatly enlarged and contain abnormal inclusions. Many of these cells are destroyed, accounting for the demyelination. Vascular changes are lacking, and inflammatory changes are present but usually insignificant.

**Clinical Features** An uncommon disease of late adult life, PML usually develops in a patient with a neoplasm or chronic immunodeficiency state. The large majority of cases are now observed in patients with AIDS in whom the incidence of PML approaches 5 percent. Viewed from another perspective, over three-quarters of cases of PML in the current era are associated with AIDS. Indeed, the incidence is so much higher than in any other form of immunosuppression that an interaction between HIV and the causative virus of PML has been suggested. Other important associations are with chronic neoplastic disease (mainly chronic lymphocytic leukemia, Hodgkin disease, lymphosarcoma, myeloproliferative disease) and, less often, with nonneoplastic granulomatosis, such as tuberculosis or sarcoidosis. A number of cases occur in patients receiving immunosuppressive drugs for renal transplantation or for other reasons. Personality changes and intellectual impairment may introduce the neurologic syndrome which evolves over a period of several days to weeks. Any one or some combination of hemiparesis progressing to quadriparesis, visual field defects, cortical blindness, aphasia, ataxia, dysarthria, dementia, confusional states, and coma are the typical manifestations (see Gillespie et al). Some of the cases under our observation had a predominantly cerebellar syndrome. Seizures are infrequent, occurring in 11 percent of cases collected by Gillespie and colleagues. In most cases death occurs in 3 to 6 months from the onset of neurologic symptoms and even more rapidly in patients with AIDS unless aggressive antiretroviral treatment is undertaken. The CSF is usually normal. CT and MRI localize the lesions with striking clarity (Fig. 33-4).

**Pathogenesis** Waksman’s original suggestion (quoted by Richardson) that PML could be due to viral infection of the CNS in patients with impaired immunologic responses proved to be correct. ZuRhein and Chou, in an electron microscopic study of cerebral lesions from a patient with PML, demonstrated crystalline arrays of particles resembling papovaviruses in the inclusion-bearing oligodendrocytes. Since then, a human polyomavirus, designated “JC virus” or JCV (initials of the patient from whom the virus was originally isolated), has definitively been shown to be the causative agent. JCV is ubiquitous, as judged by the presence of antibodies to the virus in approximately 70 percent of the normal adult population. It is thought to be dormant until an immunosuppressed state permits its active replication. The virus has been isolated from the urine, blood lymphocytes, and kidney, but there is no clinical evidence of damage to extraneural structures.

**Treatment** The disease is generally believed to be untreatable in the non-AIDS patient. Several anecdotal reports of the efficacy of cytosine arabinoside have appeared, but a controlled trial has failed to demonstrate an increased survival in AIDS patients with this disease. Interferon alpha has been thought to be beneficial in a few cases and the antiviral agent cidofovir is being tested in a large trial based on anecdotal benefit. In treated AIDS patients, aggressive treatment using antiretroviral drug combinations, including protease inhibitors, greatly slows the progression of PML and has even led to apparent remission. A review of these issues, particularly relating to AIDS and PML, is included in the report by Mangi and Miller.

![Figure 33-4. Progressive multifocal leukoencephalitis. MRI in the axial plane demonstrates multiple nonenhancing white matter lesions in a 31-year-old male with AIDS.](image-url)
Encephalitis Lethargica (Von Economo Disease, Sleeping Sickness) Although examples of a somnolent-ophthalmoplegic encephalitis dot the early medical literature (e.g., nona, fébré lethargica, Schlafkrankheit), it was in the wake of the influenza pandemic of World War I that this disease appeared prominently and continued to reappear for about 10 years. The viral agent was never identified, but the clinical and pathologic features were typical of viral infection.

The importance of encephalitis lethargica relates to its unique clinical syndromes and sequelae and to its place as the first recognized “slow virus infection” of the nervous system in human beings. The unique symptoms were ophthalmoplegia and pronounced somnolence, from which the disease took its name. Some patients were overly active, and a third group manifested a disorder of movement in the form of bradykinesia, catalepsy, mutism, chorea, or myoclonus. Lymphocytic pleocytosis was found in the spinal fluid of half the patients, together with variable elevation of the CSF protein content. More than 20 percent of the victims died within a few weeks, and many survivors were left with varying degrees of impairment of mental function. However, the most extraordinary feature was the appearance of a Parkinsonian syndrome, after an interval of weeks or months (occasionally years), in a high proportion of survivors. This is the only form of encephalitis known to cause a delayed extrapyramidal syndrome of this type (a similar though not identical syndrome with a much shorter latency may follow Japanese B encephalitis and occasionally other arboviral encephalitides, as occurred in one of our cases after Eastern equine encephalitis). Myoclonus, dystonia, oculogyric crises (page 227) and other muscle spasms, bulimia, obesity, reversal of the sleep pattern, and, in children, a change in personality with compulsive behavior were other distressing sequelae.

The pathology was typical of a viral infection, localized principally to the midbrain, subthalamus, and hypothalamus. In the patients who died years later with a Parkinson syndrome, the main findings were depigmentation of the substantia nigra and locus ceruleus due to nerve cell destruction. Neurofibrillary changes in the form of bradykinesia, catalepsy, mutism, chorea, or myoclonus. Lymphocytic pleocytosis was found in the spinal fluid of half the patients, together with variable elevation of the CSF protein content. Subacute Spongiform Encephalopathy

This category includes a quartet of human diseases—so-called Creutzfeldt-Jakob disease (and a variant that infects cows and may be rarely transmitted to humans), the Gerstmann-Strässler-Scheinker syndrome, kuru, and probably, fatal familial insomnia. Although this group of diseases has been included for discussion in the chapter on viral diseases of the nervous system, it has been evident for some time that the cause of these slow infections is neither a virus nor a viroid (nucleic acid alone, without a capsid structure). During the past 20 years, Prusiner is credited with doggedly pursuing this problem, for which he was awarded the Nobel prize. He and his colleagues have presented compelling evidence that the transmissible pathogen is a proteinaceous infectious particle that is devoid of nucleic acid, resists the action of enzymes that destroy RNA and DNA, fails to produce an immune response, and electron microscopically does not have the structure of a virus. To distinguish this pathogen from viruses and viroids, Prusiner introduced the term prion. The prion protein (PrP) is encoded by a gene on the short arm of chromosome 20. The discovery of mutations in the PrP genes of patients with familial Creutzfeldt-Jakob disease and Gerstmann-Strässler-Scheinker syndrome (described below) attests to the fact that prion diseases are both genetic and infectious. In this respect, prions are unique among all infectious pathogens. It is now possible to detect inherited types of prion disease during life, using DNA extracted from leukocytes. How prions arise in sporadic forms of spongiform encephalopathy is not fully understood; probably the conversion of the normal cellular protein to the infectious form involves a conformational change in the protein structure as described in Prusiner’s review in 2001. What is remarkable is the current theory that abnormally folded prion protein can act as a template for the conversion of normal PrP to PrPsc (the latter denoting the scrapie prion; see further on). A description of the human prion diseases follows, the most important by far being Creutzfeldt-Jakob disease.

Subacute Spongiform Encephalopathy (Creutzfeldt-Jakob Disease)

These terms refer to a distinctive cerebral disease in which a rapid progresstive and profound dementia is associated with diffuse myoclonic jerks, and a variety of other neurologic abnormalities, mainly visual or cerebellar. The major neuropathologic changes are in the cerebral and cerebellar cortices; the outstanding features are widespread neuronal loss and gliosis accompanied by a striking vacuolation or spongy state of the affected regions—hence the designation subacute spongiform encephalopathy (SSE). Less severe changes in a patchy distribution are found in cases with a briefer clinical course.

These changes, both clinical and pathologic, occur with such uniformity from case to case that they doubtless form a nosologic entity. It is generally referred to as Creutzfeldt-Jakob disease, an inappropriate eponym, since it is most unlikely that the patient described by Creutzfeldt and at least 3 of the 5 patients described by Jakob had the same disease that we now recognize as subacute
spongiform encephalopathy (SSE). It would be desirable to keep them distinct from one another, or at least, whenever one speaks of Creutzfeldt-Jakob disease, to specify what is meant—either SSE or the slower progressive dementia with signs of pyramidal and extrapyramidal affection originally described by Creutzfeldt and Jakob (the latter condition is discussed on page 913). However, decades of use makes the term Creutzfeldt-Jakob disease and its acronym, CJD, virtually impossible to displace. Precision in definition of these states is of greater importance than before, since it was shown by Gibbs and Gajdusek that brain tissue from patients with SSE, injected into chimpanzees, can transmit the disease after an incubation period of a year or longer.

**Epidemiology and Pathogenesis** The disease appears in all parts of the world and in all seasons, with an annual incidence of 1 to 2 cases per million of population. The incidence is higher in Israelis of Libyan origin, in immigrants to France from North Africa, and in Slovakia. Although the reported incidence of SSE is somewhat higher in urban than in rural areas, temporospatial clustering of cases has not been observed, at least in the United States. A small proportion of all series of cases is familial—varying from 5 percent reported by Cathala and associates to 15 percent of 1435 cases analyzed by Masters and coworkers. The occurrence of familial cases, not in the same household, suggests a genetic susceptibility to infection, although the possibility of common early exposure to the transmissible agent cannot be dismissed. A small number of conjugal cases have also been reported. The only clearly demonstrated mechanism of spread of SSE is iatrogenic, having occurred in a few cases after transplantation of corneas or dural grafts from infected individuals, after implantation of infected electroencephalograhic depth electrodes, and after the injection of human growth hormone or gonadotropins that had been prepared from pooled cadaveric sources of these hormones. At least one neurosurgeon is known to have acquired the disease. Individuals exposed to scrapie-infected sheep and to patients with SSE are not proportionately affected.

Recently, a great deal of attention has been drawn to an epidemic of prion disease among cows in the British Isles (“mad cow disease”). The epidemic began in 1985, with putative transmission of the disease to some two dozen humans. These patients have been younger (average age of onset, 27 years) than those with typical SSE (65 years) and manifested curious psychiatric and sensory symptoms as the first sign of illness; they did not exhibit the usual EEG findings even as the illness advanced to its later stages (Will et al.). This has been called “new variant Creutzfeldt-Jakob disease.” It has recently been shown that the prion strain in these patients is identical to the one from affected cattle. The mode of transmission, presumed to be the ingestion of infected meat, is reminiscent of the propagation of kuru in New Guinea by ceremonial ingestion of brain tissue from infected individuals.

Spongiform encephalopathy has now been fairly firmly associated with the conversion of a normal cellular protein, PrPc to an abnormal isoform, PrPSc. The transformation involves a change in the physical conformation of the protein in which its helical proportion diminishes and the proportion of the β pleated sheet increases (see reviews by Prusiner). Current theory holds that the “infectivity” of prions and their propagation in brain tissue may result from the susceptibility of the native prion protein to alter shape as a result of physical exposure to the abnormal protein, a so-called conformational disease. Conformationally altered prions have a tendency to aggregate, and this may be the mode of cellular destruction that leads to disease. In contrast, familial cases of prion disease are thought to be the result of one of several gene aberrations residing in the region that codes for PrPc.

Of some interest is the finding by Zanussi and colleagues of the infectious prion protein in the nasal mucosa of all nine patients studied with the sporadic disease. This suggests a route for entry into the nervous system of the aberrant prion and also a potential diagnostic test.

**Clinical Features** Transmissible SSE is in most cases a disease of late middle age, although it can occur in young adults. The sexes are affected equally. In the large series of pathologically verified cases reported by Brown and coworkers, prodromal symptoms—consisting of fatigue, depression, weight loss, and disorders of sleep and appetite lasting for several weeks—were observed in about one-third of the patients.

The early stages of the disease are characterized by a great variety of clinical manifestations, but the most frequent are changes in behavior, emotional response, and intellectual function, often followed by ataxia and abnormalities of vision, such as distortions of the shape and alignment of objects or actual impairment of visual acuity. Typically, the early phase of the disease is dominated by symptoms of confusion, with hallucinations, delusions, and agitation. In other instances, cerebellar ataxia (Brownell-Oppenheimer variant) or visual disturbances (Heidenhain variant) precede the mental changes and may be the most prominent features for several months. Headache, vertigo, and sensory symptoms are complaints in some patients but become quickly obscured by dementia and muteness.

As a rule, the disease progresses rapidly, so that obvious deterioration is seen from week to week and even day to day. Sooner or later, in almost all cases, myoclonic contractions of various muscle groups appear, perhaps unilaterally at first but later becoming generalized. Or, infrequently, the myoclonus may not appear for weeks or even months after the initial mental changes. The myoclonus is associated with a striking startle response, mainly to a loud noise. In a few patients, a startle response, which is elicitable for a brief period of time, is the only manifestation of myoclonus. In general, the myoclonic jerks are evocable by sudden sensory stimuli of all sorts (noise, bright light, touch), but they occur spontaneously as well. Twitches of individual fingers are typical but it should be emphasized that well-formed seizures are not a component of the illness. These changes gradually give way to a mute state, stupor, and coma, but the myoclonic contractions may continue to the end. Signs of degeneration of the pyramidal tracts or anterior horn cells, palsies of convergence and upgaze, and extra-pyramidal signs occur in a small number of patients as the disease advances.

The clinical diagnosis during life rests mostly on the recognition of one of the clusters of typical clinical features, particularly the unique syndrome of dementia—which progresses much more quickly than that of common degenerative diseases—coupled with stimulus-sensitive myoclonus and the characteristic EEG changes that occur in most patients (see below).

The disease is invariably fatal, usually in less than a year from the onset. In about 10 percent of patients, the illness begins with almost stroke-like suddenness and runs its course rapidly, in a matter of a few weeks. At the other extreme, a small number of patients have reportedly survived for 2 to 10 years, but these cases should be accepted with caution; in some of them, SSE appears to have been superimposed on Alzheimer or Parkinson disease or some other chronic condition that predated the prion illness.
Laboratory Diagnosis  The routine CSF and other laboratory tests are normal—useful findings in that they exclude a number of chronic inflammatory causes of dementia. In most patients, the EEG pattern is distinctive, changing over the course of the disease from one of diffuse and nonspecific slowing to one of stereotyped high-voltage slow- (1- to 2-Hz) and sharp-wave complexes on an increasingly slow and low-voltage background (see Fig. 2-3G, page 27). The high-voltage sharp waves, which give the appearance of periodicity (pseudoperiodic), are synchronous with the myoclonus but may persist in its absence. Imaging studies of the brain had been thought until recently to be of little value, but up to 80 percent of cases show a subtle hyperintensity of the lenticular nuclei on T2-weighted images when the disease is fully established (Fig. 33-5). Even more striking in some cases are the changes in diffusion-weighted imaging sequences (DWI). Long segments of the cortex as well as various parts of the basal ganglia show these alterations in a pattern that, in our experience, is characteristic and mistakable only perhaps for the appearance of diffuse cerebral anoxia (Fig. 33-5B). According to Shiga and colleagues, these changes occur in 90 percent of cases (cortex more often than caudate or lenticular nuclei and sometimes both), making them potentially the most sensitive test for the disease.

There are now helpful confirmatory diagnostic tests but they are often unnecessary. Hsich and colleagues have described a sensitive test of CSF—the finding by immunoassay of a particular peptide fragments of normal brain proteins, termed “14-3-3.” This test is particularly useful in separating SSE from other chronic non-inflammatory dementing diseases, but it has been disappointing on our wards, giving both false-positive and false-negative results. A number of other tests are emerging from specialized laboratories that detect the abnormal PrPSc isoform of the prion protein in the spinal fluid. Prusiner’s laboratory can detect eight prion strains by fluorescence immunoassay. Also, enolase and neopterin concentrations in CSF are elevated in most cases, but the release of these substances may also be found with other types of brain lesions, particularly infarction.

Tonsillar material from patients with new variant Creutzfeldt-Jakob disease (“mad cow disease”) stains with antibodies against abnormal prion protein, but this technique does not appear to be applicable to the early diagnosis of the sporadic disease (Hill). Whether the above mentioned finding of infectious prion material in the nasal mucosa will prove to have practical value in diagnosis is yet to be determined.

The National Prion Disease Pathology Surveillance Center which has been established at Case Western Reserve University is available to assist clinicians by performing, free of charge, a variety of diagnostic tests (http://www.cjdsurveillance.com).

Pathology  The disease affects principally the cerebral and cerebellar cortices, generally in a diffuse fashion, although in some cases the occipitoparietal regions are almost exclusively involved, as in those described by Heidenhain. In others, such as the cases of Brownell and Oppenheimer, the cerebellum has been most extensively affected, with early and prominent ataxia. The degeneration and disappearance of nerve cells is associated with extensive astrogial proliferation; ultrastructural studies have shown that the microscopic vacuoles, which give the tissue its typically spongiform appearance, are located within the cytoplasmic processes of glial cells and dendrites of nerve cells. The loss in particular of certain inhibitory neurons in the thalamic reticular nuclei corresponds to the presence of myoclonus and positive sharp waves in the EEG, according to Tschampa and colleagues. Despite the fact that the disease is due to a transmissible agent, the lesions show no evidence of an inflammatory reaction and no viral particles are seen.

Differential Diagnosis  The diagnosis of most cases of SSE presents no difficulty. Not infrequently, however, we have been surprised by a “typical” case that proves to be some other disease. Lithium intoxication, Hashimoto encephalopathy (as emphasized by Seipelt who found a number of cases in an epidemiologic survey of SSE (page 978), Whipple disease (page 603), intravascular lymphoma, carcinomatous meningitis—all of them characterized by myoclonus and dementia—may mimic SSE in the early weeks of illness. Contrariwise, the early mental changes of SSE may be
misinterpreted as an atypical or unusually intense emotional reaction, as one of the major psychoses, as an unusual form of Alzheimer disease with myoclonus, or as Lewy body disease. Despite the designation of SSE as a progressive dementia, the similarities to even rapidly developing Alzheimer disease are superficial. Also, diagnosis may be difficult in patients who present with dizziness, gait disturbance, diplopia, or visual disturbances until the rapidly evolving clinical picture clarifies the issue. Subacute sclerosing panencephalitis (see above), in its fully developed form, may resemble SSE, but the former is chiefly a disease of children or young adults, and the CSF shows elevation of gamma globulin (IgG), whereas the latter is essentially a disease of middle age and the presenile period, and the CSF is normal. Limbic-brainstem-cerebellar encephalitis in patients with an occult tumor and AIDS dementia (discussed earlier) also figure in the differential diagnosis. Cerebral lipidosis in children or young adults can result in a similar combination of myoclonus and dementia, but the clinical course in such cases is extremely chronic and there are retinal changes that do not occur in SSE. Well-formed convulsions should direct attention to a diagnosis other than SSE.

**Management**  No specific treatment is known. Antiviral agents have been ineffective. In view of the transmissibility of the disease from humans to primates and iatrogenically from person to person with infected materials, certain precautions should be taken in the medical care of and handling of materials from patients with SSE. Special isolation rooms are not necessary, and the families of affected patients and nursing staff can be reassured that casual contact poses no risk. Needle punctures and cuts are not thought to pose a risk but some uncertainty remains. The transmissible agent is resistant to boiling, treatment with formalin and alcohol, and ultraviolet radiation but can be inactivated by autoclaving at 132°C at 15 lb/in.² for 1 h or by immersion for 1 h in 5% sodium hypochlorite (household bleach). Workers exposed to infected materials (butchers, abattoir workers, health care workers) should wash thoroughly with ordinary soap. Needles, glassware, needle electrodes, and other instruments should be handled with great care and immersed in appropriate disinfectants and autoclaved or incinerated. The performance of a brain biopsy or autopsy requires that a set of special precautions be followed, as outlined by Brown (see References). Obviously such patients or any others known to have been demented should not be donors of organs for transplantation or blood for transfusion.

**Gerstmann-Sträussler-Scheinker Syndrome**  This is a rare, strongly familial disease inherited as an autosomal dominant trait. It begins insidiously in midlife and runs a chronic course (mean duration, 5 years). The main characteristics are a progressive cerebellar ataxia, corticospinal tract signs, dysarthria, and nystagmus. Dementia is often associated but is relatively mild. There are characteristic spongiform changes, as in SSE.

Brain tissue from patients with this disease, when inoculated into chimpanzees, has produced a spongiform encephalopathy (Masters et al). Molecular genetic studies of affected members demonstrate a mutation of the prion protein gene. This syndrome should be considered as a small familial subset of SSE, of slowly progressive type.

**Fatal Familial Insomnia**  This is another very rare familial disease; it is characterized by intractable insomnia, sympathetic overactivity, and dementia, leading to death in 7 to 15 months (see also page 340). The pathologic changes, consisting of neuronal loss and gliosis, are found mainly in the medial thalamic nuclei. Studies of a few families have shown a mutation of the prion protein gene, and brain material was found to contain a protease-resistant form of the gene. Transmission of the disease by inoculation of infected brain material has not been accomplished (Medori et al).

**Kuru**  This disease, which occurs exclusively among the Fore linguistic group of natives of the New Guinea highlands, was the first slow infection due to a nonconventional transmissible agent to be documented in human beings. Clinically the disease takes the form of an afibrile, progressive cerebellar ataxia, with abnormalities of extraocular movements, weakness progressing to immobility, incontinence in the late stages, and death within 3 to 6 months of onset. In some ways it is similar to the ataxic (Brownell-Oppenheimer) variant of Creutzfeldt-Jakob disease. The remarkable epidemiologic and pathologic similarities between kuru and scrapie were pointed out by Hadlow (1959), who suggested that it might be possible to transmit kuru to subhuman primates. This was accomplished in 1966 by Gajdusek and coworkers; inoculation of chimpanzees with brain material from affected humans produced a kuru-like syndrome in chimpanzees after a latency of 18 to 36 months. Since then the disease has been transmitted from one chimpanzee to another and to other primates by using both neural and nonneural tissues. The pioneering work in this field led to the awarding of a Nobel Prize. Histologically there is a noninflammatory loss of neurons and spongiform change throughout the brain, but predominantly in the cerebellar cortex, with astrogial proliferation and PAS-positive stellate plaques of amyloid-like material (“kuru plaques”). The transmissible agent has not been visualized, however.

Kuru has gradually disappeared, apparently because of the cessation of ritual cannibalism by which the disease had been transmitted. In this ritual, infected brain tissue was ingested and rubbed over the body of the victim’s kin (women and young children of either sex), permitting absorption of the infective agent through conjunctivae, mucous membranes, and abrasions in the skin.

CHAPTER 33 VIRAL INFECTIONS OF THE NERVOUS SYSTEM, CHRONIC MENINGITIS, PRION DISEASES

Among all the neurologic diseases of adult life, the cerebrovascular ones clearly rank first in frequency and importance. At least 50 percent of the neurologic disorders in a general hospital are of this type. At some time or other, every physician will be required to examine patients with cerebrovascular disease and should at least know something of the common types—particularly those in which there is a reasonable prospect of successful medical or surgical intervention or the prevention of recurrence. There is another advantage to be gained from the study of this group of diseases—namely, that they have traditionally provided one of the most instructive approaches to neurology. As our colleague C. M. Fisher has aptly remarked, house officers and students learn neurology literally “stroke by stroke.” Moreover, the focal ischemic lesion has divulged some of our most important ideas about the function of the human brain.

It must also be noted that, in the last two decades, new and extraordinary types of imaging technology have been introduced that allow the physician to make physiologic distinctions between normal, ischemic, and infarcted brain tissue. This biopathologic approach to stroke will likely guide the next generation of treatments and has already had a pronounced impact on the direction of research in the field. Salvageable brain tissue to be protected in the acute phase of stroke can be delineated by these methods. To identify this ischemic but not yet infarcted tissue virtually defines the goal of modern stroke treatment. Which of the sophisticated imaging techniques will contribute to improved clinical outcome is still to be determined, but certain ones, such as diffusion-weighted imaging, have already proved invaluable in stroke work.

Despite these valuable advances in stroke neurology, three points should be made. First, all physicians have a role to play in the prevention of stroke by encouraging the reduction in risk factors such as hypertension and the identification of signs of potential stroke, such as transient ischemic attacks, atrial fibrillation, and carotid artery stenosis. Second, careful bedside clinical evaluation integrated with the newer testing methods mentioned above still provide the most promising approach to this category of disease. Finally, the last decade or two have witnessed a departure from the more basic or primary disorder, i.e., atherosclerosis, hypertensive arteriosclerotic change, arteritis, aneurysmal dilation, and developmental malformation. Equal importance attaches to the second-ary parenchymal changes in the brain resulting from the vascular disease. The term pathologic process may be considered not only in its grosser aspects—embolism, thrombosis, dissection, or rupture of a vessel—but also in terms of the more basic or primary disorder, i.e., atherosclerosis, hypertensive arteriosclerotic change, arteritis, aneurysmal dilation, and developmental malformation. Equal importance attaches to the secondary parenchymal changes in the brain resulting from the vascular lesion. These are of two main types—infarction, with or without hemorrhage—and unless one or the other occurs, the vascular lesion usually remains silent. The only exceptions to this statement are the local pressure effects of an aneurysm, vascular headache (migraine, hypertension, temporal arteritis), multiple small vessel disease with progressive encephalopathy (as in malignant hypertension or cerebral arteritis), and increased intracranial pressure (as occurs in hypertensive encephalopathy and venous sinus thrombosis). Also, persistent acute hypotension may cause ischemic necrosis in regions of brain between the vascular territories of cortical vessels, even without vascular occlusion. The many types of cerebrovascular diseases are listed in Table 34-1, and the predominant types during each period of life, in Table 34-2.

Definition of Terms

As discussed below, the term stroke is applied to a sudden focal neurologic syndrome, specifically the type due to cerebrovascular disease. The term cerebrovascular disease designates any abnormality of the brain resulting from a pathologic process of the blood vessels. Pathologic process is given an inclusive meaning—namely, occlusion of the lumen by embolus or thrombus, rupture of a vessel, an altered permeability of the vessel wall, or increased viscosity or other change in the quality of the blood flowing through the cerebral vessels. The vascular pathologic process may be considered not only in its grosser aspects—embolism, thrombosis, dissection, or rupture of a vessel—but also in terms of the more basic or primary disorder, i.e., atherosclerosis, hypertensive arteriosclerotic change, arteritis, aneurysmal dilation, and developmental malformation. Equal importance attaches to the secondary parenchymal changes in the brain resulting from the vascular lesion. These are of two main types—infarction, with or without hemorrhage—and unless one or the other occurs, the vascular lesion usually remains silent. The only exceptions to this statement are the local pressure effects of an aneurysm, vascular headache (migraine, hypertension, temporal arteritis), multiple small vessel disease with progressive encephalopathy (as in malignant hypertension or cerebral arteritis), and increased intracranial pressure (as occurs in hypertensive encephalopathy and venous sinus thrombosis). Also, persistent acute hypotension may cause ischemic necrosis in regions of brain between the vascular territories of cortical vessels, even without vascular occlusion. The many types of cerebrovascular diseases are listed in Table 34-1, and the predominant types during each period of life, in Table 34-2.
Table 34-1
Causes of cerebral abnormalities from alterations of arteries and veins

1. Atherosclerotic thrombosis
2. Transient ischemic attacks
3. Embolism
4. Hypertensive hemorrhage
5. Ruptured or unruptured saccular aneurysm or AVM
6. Arteritis
   a. Meningovascular syphilis, arteritis secondary to pyogenic and tuberculous meningitis, rare infective types (typhus, schistosomiasis, malaria, mucormycosis, etc.)
   b. Connective tissue diseases (polyarteritis nodosa, lupus erythematosus), necrotizing arteritis. Wegener arteritis, temporal arteritis, Takayasu disease, granulomatus or giant-cell arteritis of the aorta, and giant-cell granulomatus angitis of cerebral arteries
7. Cerebral thrombophlebitis: secondary to infection of ear, paranasal sinus, face, etc.; with meningitis and subdural empyema; debilitating states, postpartum, postoperative, cardiac failure, hematologic disease (polycythemia, sickle cell disease), and of undetermined cause
8. Hematologic disorders: anticoagulants and thrombolytics, clotting factor disorders, polycythemia, sickle cell disease, thrombotic thrombocytopenic purpura, thrombocytosis, intravascular lymphoma, etc.
9. Trauma and dissection of carotid and basilar arteries
10. Amyloid angiopathy
11. Dissecting aortic aneurysm
12. Complications of arteriography
13. Neurologic migraine with persistent deficit
14. With tentorial, foramen magnum, and subfalcial herniations
15. Miscellaneous types: fibromuscular dysplasia, with local dissection of carotid, middle cerebral, or vertebrobasilar artery, x-irradiation, unexplained middle cerebral infarction in closed head injury, pressure of unruptured saccular aneurysm, complication of oral contraceptives
16. Undetermined cause in children and young adults: moyamoya disease and others

More than any other organ, the brain depends from moment to moment on an adequate supply of oxygenated blood. Constancy of the cerebral circulation is assured by a series of baroreceptors and vasomotor reflexes under the control of centers in the lower brainstem. In Stokes-Adams attacks, for example, unconsciousness occurs within 10 s of the beginning of asystole. In animal experiments and probably in humans, the complete stoppage of blood flow for longer than 5 min produces irreversible damage. Brain tissue deprived of blood undergoes ischemic necrosis or infarction (also referred to as a zone of softening or encephalomalacia). Obstruction of an artery by thrombus or embolus is the usual cause of focal ischemic damage, but failure of the circulation and hypotension from cardiac decompensation or shock, if severe and prolonged enough, can produce focal as well as diffuse ischemic changes.

Cerebral infarcts vary greatly in the amount of congestion and hemorrhage found within the softened tissue. Some infarcts are devoid of blood and therefore pallid (pale infarction); others show mild congestion (dilatation of blood vessels and escape of red blood cells), especially at their margins; still others show an extensive extravasation of blood from many small vessels all through the infarcted tissue (red or hemorrhagic infarction). Some infarcts are all of one type, either pale or hemorrhagic; many are mixed. The reason for the occurrence of hemorrhagic infarction—almost always, occurring in cases of cerebral embolism—is not fully un-

Table 34-2
Cerebrovascular diseases characteristic of each age period

1. Prenatal circulatory diseases leading to
   a. Porencephaly
   b. Hydranencephaly
   c. Hypoxic-ischemic damage
   d. Unilateral cerebral infarction
2. Perinatal and postnatal circulatory disorders resulting in
   a. Cardiorespiratory failure and generalized ischemia—état marbre
   b. Periventricular infarcts
   c. Matrix hemorrhages and ischemic foci in premature infants
   d. Hemorrhagic disease of the newborn
3. Infancy and childhood: vascular diseases associated with
   a. Ischemic infarction
   b. Congenital heart disease and paradoxical embolism
   c. Moyamoya
   d. Bacterial endocarditis, rheumatic fever, lupus erythematosus
   e. Sickle cell anemia
   f. Mitochondrial disorders (MELAS')
   g. Homocystinuria and Fabry’s angiokeratosis
4. Adolescence and early adult life: vascular occlusion or hemorrhage with
   a. Pregnancy and puerperium
   b. Estrogen-related stroke
   c. Migraine
   d. Vascular malformations
   e. Premature atherosclerosis
   f. Arteritis
   g. Valvular heart disease
   h. Sickle cell anemia
   i. Antiphospholipid arteriopathy, plasma C-protein deficiency and other coagulopathies
   j. Moyamoya, Takayasu disease
   k. Arterial dissections
   l. Amyloid angiopathy
5. Middle age
   a. Atherosclerotic thrombosis and embolism
   b. Cardiogenic embolism

understood. The explanation most consistent with our observations is that embolic material, after occluding an artery and causing ischemic necrosis of brain tissue, then fragments and migrates distally from its original site. This allows partial restoration of the circulation to the infarcted zone, and blood seeps through the damaged small vessels (Fisher and Adams). In such cases, one often cannot find the embolus by arteriography or postmortem examination, or one finds only a few fragments proximal to the pale ischemic zones.

Cerebral hemorrhage is one of two types. In the intracerebral variety, blood leaks from the vessel (usually a small artery) directly into the brain, forming a hematoma in the brain substance and sometimes spreading into the ventricles and then to the subarachnoid space. Once the leakage is arrested, the blood slowly disintegrates and is absorbed over a period of weeks and months. The mass of clotted blood causes physical disruption of the tissue and pressure on the surrounding brain. The second type of bleeding originates from an aneurysmal dilatation at branching points of the large arteries of the circle of Willis; the bleeding is almost exclusively contained within the subarachnoid spaces and therefore, causes little immediate focal effect on the brain. In this way, subarachnoid hemorrhage differs from other stroke syndromes. However, blood within the subarachnoid space, if large in quantity, may cause a delayed cerebral ischemia through a mechanism of constriction of the vessels of the circle of Willis and their primary branches (vasospasm). In addition to these two main types of hemorrhage, a bland infarction in many instances has areas of leakage of blood into the brain, so-called hemorrhagic infarction.

THE STROKE SYNDROME

So distinctive is the clinical presentation of cerebrovascular disease that the diagnosis is seldom in doubt. The common mode of expression is the stroke, defined as the sudden occurrence of a nonconvulsive, focal neurologic deficit. In its most severe form the patient becomes hemiplegic or even comatose—an event so dramatic that it had been given its own designations, namely apoplexy, cerebrovascular accident (CVA), or shock (colloquial). However, stroke is the currently preferred term. In its mildest form it may consist of a trivial neurologic disorder insufficient for the patient even to seek medical attention. There are all gradations of severity between these two extremes, but in all forms of stroke the denotative feature is the temporal profile of neurologic events. It is the abruptness with which the neurologic deficit develops—a matter of seconds or minutes—that stamps the disorder as vascular. Embolic strokes characteristically occur suddenly, and the deficit reaches its peak almost at once. Thrombotic strokes may have a similarly abrupt onset, but they evolve somewhat more slowly over a period of several minutes or hours and occasionally days; in the latter case, the stroke usually progresses in a saltatory fashion, i.e., in a series of steps rather than smoothly. In hypertensive cerebral hemorrhage, also abrupt in onset, the deficit may be virtually static or steadily progressive over a period of minutes or hours, while subarachnoid hemorrhage is almost instantaneous.

The other important aspect of the temporal profile is the arrest and then regression of the neurologic deficit in almost all except the fatal strokes. At one extreme of rapid regression is a focal syndrome that reverses itself entirely and dramatically over a period of minutes or up to an hour; this defines the “transient ischemic attack” (TIA). Not infrequently, an extensive deficit from embolism reverses itself within a few hours or days. More often, and this is the case in most thrombotic strokes, improvement occurs gradually over weeks and months, and the residual disability is considerable. A gradual downhill course over a period of several days or weeks will usually be traced to a nonvascular disease. The only exceptions are the additive effects of multiple vascular occlusions (platelet thrombosis, lupus erythematosus, and other arteritides; see Table 34-1) and the progressive brain edema surrounding large infarctions and cerebral hemorrhages.

The neurologic deficit reflects both the location and the size of the infarct or hemorrhage. Hemiplegia stands as the classic sign of all cerebrovascular diseases, whether in the cerebral hemisphere or brainstem, but there are many other manifestations, occurring in large but highly recognizable combinations. These include mental confusion, numbness and sensory deficits of many types, aphasia, visual field defects, diplopia, dizziness, dysarthria, and so forth. The neurovascular syndromes that they form enable the physician to localize the lesion—sometimes so precisely that even the affected arterial branch can be specified—and to indicate whether the lesion is an infarct or a hemorrhage. These neurovascular syndromes are described in the section that follows.

It would be incorrect to assume that every cerebrovascular illness expresses itself as a clearly delineated stroke. Some lesions are clinically silent or cause disorders of function so mild as to concern the patient little if at all. Neither the patient nor the family can then date the onset of the illness. Other small incidents may become sources of complaint only when their cumulative effects become manifest. Sometimes, stenosis of the common or internal carotid results in a chronic marginally low blood flow, which, by fluctuating during physical activity, may diminish vision or induce a defect in sensory or motor function or an abnormality of movement. Another problem is that certain dominant hemispheric lesions cause aphasic disturbances, which hamper history taking, and nondominant ones cause anosognosia, in which the patient is unaware of his deficits or denies them—hence his descriptions are close to useless.

Imaging techniques, as already alluded to, continue to enhance the clinical study of stroke patients; they allow the demonstration of both the cerebral lesion and the affected blood vessel. CT scanning demonstrates and accurately localizes even small hemorrhages, hemorrhagic infarcts, subarachnoid blood, clots in and around aneurysms, regions of infarct necrosis and arteriovenous malformations. Magnetic resonance imaging (MRI) also demonstrates these lesions and, in addition, reveals flow voids in vessels, hemosiderin and iron pigment, and the alterations resulting from ischemic necrosis and gliosis. Of the two procedures, MRI is particularly advantageous in demonstrating small lacunar lesions deep in the hemispheres and abnormalities in the brainstem (a region obscured by adjacent bone in CT scans). One of the diagnostic advances in the last decade has been the introduction of the diffusion-weighted technique, which allows the early detection of an infarctive lesion within minutes of the stroke, i.e., considerably earlier than CT and MRI scan (Fig. 34-1). The various MRI imaging sequences used in the diagnosis and dating of stroke are discussed below and in Chap. 2.

Other ancillary procedures for the investigation of cerebrovascular disease include Doppler ultrasound flow studies, which demonstrate atheromatous plaques and stenoses of large vessels, particularly of the carotid but also the vertebralbasilar arteries. The transcranial Doppler technique has reached a degree of precision whereby occlusion or spasm of the main vessels of the circle of Willis can be seen. Arteriography, now enhanced by digital processing of images, most accurately demonstrates stenoses and oc-
Figure 34-1. Diffusion-weighted image (DWI) showing a large right middle cerebral artery infarction (left) and the corresponding magnetic resonance angiogram (right) demonstrating that the vessel is occluded at its proximal portion. The DWI bright signal changes are evident well before alterations are seen in the CT or MRI.

clusions of the larger vessels as well as aneurysms, vascular malformations, and other blood vessel diseases such as arteritis. To a large degree, conventional dye-injection angiography has been supplanted by magnetic resonance angiography (MRA; Fig. 34-1) and venography (MRV) for the visualization of large intracranial arteries and veins; these have the advantage of safety but do not yet give refined images of the smaller vessels and are not as accurate as angiography in measuring the severity of stenosis of a vessel. New CT techniques called spiral CT angiography now offer images of better resolution, comparable to conventional arteriograms. They have the additional advantage of demonstrating soft tissues and bone adjacent to these vessels, thus providing the surgeon with important anatomic information (see Chap. 2). Lumbar puncture indicates whether blood has entered the subarachnoid space (from aneurysm, vascular malformation, hypertensive hemorrhage, and some instances of hemorrhagic infarction). The cerebrospinal fluid (CSF) is clear in cases of “pale” infarction from thrombosis and embolism. In most stroke cases, the CT scan or MRI, neither of which entails any risk to the patient, precludes the need for lumbar puncture and conventional angiography.

The electroencephalogram (EEG) has lost favor in stroke diagnosis but is probably underutilized as a readily available means of detecting cortical infarction in the wake of ischemia of a region of one hemisphere. It allows a distinction to be made between occlusion of a small and a large vessel, because focal EEG abnormalities are sparse or absent with a deep lacunar stroke. The EEG is most useful soon after the stroke, when the only available alternative is the CT scan, which often does not visualize the infarct until several days have passed.

Risk Factors for Stroke

Several factors are known to increase the liability to stroke, and it has been here that large-scale public health measures have had a substantial influence. The most important of these are hypertension, heart disease, atrial fibrillation, diabetes mellitus, cigarette smoking, and hyperlipidemia. Others, such as systemic diseases associated with a hypercoagulable state and the use of birth control pills, also contribute, but only in special circumstances. Hypertension is the most readily recognized factor in the genesis of primary intracerebral hemorrhage. It appears that the stroke-producing potential of hypertension is as much the product of heightened systolic pressure as of diastolic pressure (Fisher; Rabkin et al). The cooperative studies of the Veterans Administration (see Freis et al) and the report by Collins and associates (collating 14 randomized trials of antihypertensive drugs) have convincingly demonstrated that the long-term control of hypertension decreases the incidence of both atherothrombotic infarction and intracerebral hemorrhage. And simple measures such as the use of hydrochlorothiazide for blood pressure control may be overall the most effective. The presence of congestive heart failure and coronary atherosclerosis also greatly increases the probability of stroke. As for embolic strokes, the most important risk factors are structural cardiac disease and arrhythmias, particularly atrial fibrillation, which increases the incidence of stroke about six-fold, and by eighteen-fold if there is also rheumatic valvular disease. Bacterial and nonbacterial (marantic) endocarditis and right-to-left shunts between the cardiac chambers or in the lung also predispose to embolic stroke. Diabetes hastens the atherosclerotic process in both large and small arteries; Weinberger and colleagues and Roehmholdt and coworkers have found diabetic patients to be twice as liable to stroke as age-matched nondiabetic groups. Also, Homer and Ingall and their colleagues have documented the importance of long-duration cigarette smoking in the development of carotid atherosclerosis. The interactions between diabetes and hypertension on the one hand and intracerebral hemorrhage and atherothrombotic infarction on the other—as well as the association of cardiac disease and cerebral embolism—are considered further on in this chapter, in relation to
each of these categories of cerebrovascular disease. Subsidiary factors, such as low potassium intake and reduced serum levels of potassium, have been associated with an increased stroke rate in several studies, including one that we conducted, but the mechanism of this effect is obscure (Green et al); a detrimental effect on blood pressure is possible. Numerous clinical trials have also shown a marked reduction in stroke incidence with the use of cholesterol-lowering drugs. Public health measures designed to detect and reduce the aforementioned risk factors offer the most intelligent long-range approach to the prevention of cerebrovascular disease.

Ischemic Stroke

Focal cerebral ischemia differs fundamentally from global ischemia. In the latter state, if absolute, there is no cerebral blood flow of the entire brain and irreversible destruction of neurons occurs within 4 to 8 min at normal body temperature. In focal ischemia, there is nearly always some degree of circulation (via collateral vessels), permitting to a varying extent the delivery of oxygenated blood and glucose.

The effects of a focal arterial occlusion on brain tissue also vary depending on the location of the occlusion in relation to available collateral and anastomotic channels. If the obstruction lies proximal to the circle of Willis (toward the heart), the anterior and posterior communicating arteries of the circle are often adequate to prevent infarction. In occlusion of the internal carotid artery in the neck, there may be anastomotic flow from the external carotid artery through the ophthalmic artery or via other smaller external-internal connections (Fig. 34-2). With blockage of the vertebral artery, the anastomotic flow may be via the deep cervical, thyrco-cervical, or occipital arteries or retrograde from the other vertebral artery. If the occlusion is in the stem portion of one of the cerebral arteries, i.e., distal to the circle of Willis, a series of meningeal interarterial anastomoses may carry sufficient blood into the compromised territory to lessen (rarely to prevent) ischemic damage (see Figs. 34-2 and 34-3). There is also a capillary anastomotic system between adjacent arterial branches, and although it may reduce the size of the ischemic field, particularly of the penetrating arteries, it is usually not significant in preventing infarction. Thus, in the event of occlusion of a major arterial trunk, the extent of infarction ranges from none at all to the entire vascular territory of that vessel. Between these two extremes are all degrees of variation in the extent of infarction and its degree of completeness.

Additional ischemia-modifying factors determine the extent of necrosis. The speed of occlusion assumes importance; gradual narrowing of a vessel allows time for collateral channels to open. The level of blood pressure may influence the result; hypotension at a critical moment may render anastomotic channels ineffective. Hypoxia and hypercapnia are presumed to have deleterious effects. Altered viscosity and osmolality of the blood and hyperglycemia are potentially important factors but difficult to evaluate. Finally, anomalies of vascular arrangement (of neck vessels, circle of Willis, and surface arteries) and the existence of previous vascular occlusions must influence the outcome.

The specific neurologic deficit obviously relates to the location and size of the infarct or focus of ischemia. The territory of any artery, large or small, deep or superficial, may be involved. When an infarct lies in the territory of a carotid artery, as would be expected, unilateral signs predominate: hemiplegia, hemianesthesia, hemianopia, aphasia, and agnosias are the usual consequences. In the territory of the basilar artery, the signs of infarction are frequently bilateral and occur in conjunction with cranial nerve palsies and other segmental brainstem and cerebellar signs; quadriplegia, hemiparesis, and/or unilateral or bilateral sensory impairment are typical, coupled with diplopia, dysarthria, and vertigo in various combinations.

Pathophysiology of Cerebral Ischemia and Ischemic Infarction

Cerebral infarction basically comprises two pathophysiologic processes—one, a loss in the supply of oxygen and glucose secondary to vascular occlusion, and the other, an array of changes in cellular metabolism consequent to the collapse of energy-producing processes, ultimately with disintegration of cell membranes. Of potential therapeutic importance are the observations that some of the cellular processes leading to neuronal death are not irrevocable and may be reversed by early intervention, either through restoration of blood flow, by prevention of the influx of calcium into cells, or by interfering intermediatory processes involved in cell death.

Vascular Factors At the center of an ischemic stroke is a zone of infarction. The necrotic tissue swells rapidly, mainly because of excessive intracellular and intercellular water content. Since anoxia also causes necrosis and swelling of cerebral tissue (although in a different distribution), oxygen lack must be a factor common to both infarction and anoxic encephalopathy. The effects of ischemia, whether functional and reversible or structural and irreversible, depend on its degree and duration. The margins of the infarct are hyperemic, being nourished by meningeal collaterals, and here there is only minimal or no parenchymal damage.

If the brain is observed at the time of arterial occlusion, the venous blood is first seen to darken, owing to an increase in reduced hemoglobin. The viscosity of the blood and resistance to flow both increase, and there is sludging of formed elements within vessels. The tissue becomes pale. Arteries and arterioles become narrowed, especially in the pale areas. Upon re-establishing flow in the occluded artery, the sequence is reversed and there may be a slight hyperemia. If the ischemia is prolonged, sludging and endothelial damage prevent normal reflow (the “no-reflow” phenomenon described below).

These flow factors have been studied in experimental animals by Heiss and by Siesjo and others and are reviewed in detail by Hossman. These investigators have determined the critical threshold of cerebral blood flow (CBF), measured by xenon clearance, below which functional impairment occurs. In several animal species, including macaque monkeys and gerbils, the critical level was 23 mL/100 g/min (normal is 55 mL); if, after short periods of time, CBF is restored to higher levels the impairment of function can be reversed. Reduction of CBF below 10 to 12 mL/100 g/min causes infarction, almost regardless of its duration. The critical level of hypoperfusion that abolishes function and leads to tissue damage is therefore a CBF between 12 and 23 mL/100 g/min. At these levels of blood flow the EEG is slowed, and below this level it becomes isoelectric. In the region of marginal perfusion (“ischemic penumbra”), the K level increases (efflux from injured depolarized cells) and ATP and creatine phosphate are depleted. These biochemical abnormalities are reversible if the circulation is restored to normal. Disturbance of calcium ion homeostasis and accumulation of free fatty acids interfere with full recovery. A CBF of 6 to 8 mL/100 g/min causes marked ATP depletion, increase in extracellular K, increase in intracellular Ca, and cellular acidosis,
CHAPTER 34 CEREBROVASCULAR DISEASES

**Figure 34-2.** Arrangement of the major arteries on the right side carrying blood from the heart to the brain. Also shown are collateral vessels that may modify the effects of cerebral ischemia. For example, the posterior communicating artery connects the internal carotid and the posterior cerebral arteries and may provide anastomosis between the carotid and basilar systems. Over the convexity, the subarachnoid interarterial anastomoses linking the middle, anterior, and posterior cerebral arteries are shown, with insert A illustrating that these anastomoses are a continuous network of tiny arteries forming a border zone between the major cerebral arterial territories. Occasionally a persistent trigeminal artery connects the internal carotid and basilar arteries proximal to the circle of Willis, as shown in insert B. Anastomoses between the internal and external carotid arteries via the orbit are illustrated in insert C. Wholly extracranial anastomoses from muscular branches of the cervical arteries to vertebral and external carotid arteries are indicated in insert D.

leading invariably to histologic signs of necrosis. These changes do not become apparent for several hours. Free fatty acids (appearing as phospholipases) are activated and destroy the phospholipids of neuronal membranes. Prostaglandins, leukotrienes, and free radicals accumulate, and intracellular proteins and enzymes are denatured. Cells then swell, a process called *cellular*, or *cytotoxic*, *edema* (see page 550). Similar abnormalities affect mitochondria, even before other cellular changes are evident.

Implicit in all discussions of ischemic stroke and its treatment is the existence of a “penumbra” zone that is marginally perfused and contains viable neurons. Presumably this zone exists at the margins of an infarction, which at its core has irrevocably damaged tissue that is destined to become necrotic. Using various methods, such a penumbra can be demonstrated in association with some infarctions but not all, and the degree of reversible tissue damage is difficult to determine. The neurons in the penumbra are consid-

Figure 34-3. Diagram of the brainstem showing the principal vessels of the vertebrobasilar system (the circle of Willis and its main branches). The term M1 is used to refer to the initial (stem) segment of the middle cerebral artery; A1 to the initial segment of the anterior cerebral artery proximal to the anterior communicating artery; A2 to the post-communal segment of the anterior cerebral artery; and P1 and P2 to the corresponding pre- and postcommunal segments of the posterior cerebral artery.

The letters and arrows on the right indicate the levels of the four cross sections following: A = Fig. 34-16; B = Fig. 34-15; C = Fig. 34-14; D = Fig. 34-13.

Although vascular syndromes of the pons and medulla have been designated by sharply outlined shaded areas, one must appreciate that since satisfactory clinicopathologic studies are scarce, the diagrams do not always represent established fact. The frequency with which infarcts fail to produce a well-recognized syndrome and the special tendency for syndromes to merge with one another must be emphasized.

Metabolic Factors

Interest has focused on the role of excitatory neurotransmitters, particularly glutamate and aspartate, which are formed from glycolytic intermediates of the Krebs cycle. It has been found that these neurotransmitters, released by ischemic cells, excite neurons and produce an intracellular influx of Na and Ca. These changes are said to be responsible for irreversible cell injury. This is presently a subject of active biochemical and clinical research. Some current attempts at therapy, for example, are directed at limiting the extent of infarction by blocking the glutamate receptor, particularly the NMDA (N-methyl-D-aspartate) channel—
one of several calcium channels that open under conditions of ischemia and set in motion a cascade of cellular events, eventuating in neuronal death. However, even complete blockade of the NMDA channels has so far not prevented cellular death, presumably because dysfunction of several other types of calcium channels continues. Novel strategies have been suggested to prevent calcium influx, but the drugs that block the various calcium channels seem to work only if given before the stroke, making this approach impractical in most situations. Additional biochemical events must be induced by ischemia, including the production of free radicals, which leads to peroxidation and disruption of the outer cell membrane. Clearly, the cascade of intracellular events that lead to neu-
neurovascular syndromes. The clinical picture that results from an occlusion of any one artery differs in minor ways from one patient to another, but there is sufficient uniformity to justify the assignment of a typical syndrome to each of the major arteries and their branches. The following descriptions apply particularly to the clinical effects of ischemia and infarction due to embolism and thrombosis. The identification of these effects is one of cardinal skills of the clinical neurologist. Although hemorrhage within a specific vascular territory may give rise to many of the same effects, the total clinical picture is different because it usually involves regions supplied by more than one artery and, by its deep extension and pressure effects, causes secondary features of headache, vomiting, and hypertension as well as a series of falsely localizing signs, as described in Chaps. 17 and 31.

The Carotid Artery

The carotid system consists of three major arteries—the common carotid, internal carotid, and external carotid. As indicated in Fig. 34-2, the right common carotid artery arises at the level of the sternoclavicular notch from the innominate (brachiocephalic) artery, and the left common carotid comes directly from the aortic arch. The common carotids ascend in the neck to the C4 level, just below the angle of the jaw, where each divides into external and internal branches (sometimes the bifurcation is slightly above or below this point).

Common carotid occlusion accounts for less than 1 percent of cases of carotid artery syndrome—the remainder being due to disease of the internal carotid artery itself. Nevertheless, the common carotid can be occluded by an atheromatous plaque at its origin, more often on the left side. Atherosclerotic stenosis or occlusion of the midportion of the common carotid may also occur years after radiation therapy for laryngeal or other head and neck cancer. If the bifurcation is patent, few if any symptoms may result, in some cases because retrograde flow from the external carotid maintains internal carotid flow and perfusion of the brain.

Because the syndromes caused by common carotid occlusion are identical to those of its internal branch, the remainder of this discussion is concerned with disease of the internal carotid artery. The territory supplied by this vessel and its main branches is shown in Figs. 34-4, 34-5, and 34-6. The clinical manifestations of atherothrombotic disease of this artery are among the most variable of any cerebrovascular syndrome. Unlike other cerebral vessels, the internal carotid artery is not an end vessel. In most individuals it is in continuity with the vessels of the circle of Willis and those of the orbit, and no part of the brain is completely dependent on it. Therefore occlusion, which occurs most frequently in the first part of the internal carotid artery (immediately beyond the carotid bifurcation), is often silent (30 to 40 percent of cases).

There are two mechanisms by which strokes arise from atherosclerosis and superimposed thrombotic occlusion of the internal carotid artery. (We use the terms "atherothrombotic" and "atherothrombosis" here and in subsequent sections of the chapter to indicate this common mechanism of local stenosis, which leads to occlusion of the proximal parts of cerebral vessels or at their origins in the thorax and neck; see page 686). First, occlusion of the carotid may give rise to an embolus that passes distally in the territory of its tributary vessels, downstream from the internal carotid artery (middle and anterior cerebral arteries and their branches, as described further on). This has been termed "artery-to-artery embolism." Second, and less often, occlusion of the carotid artery may lead to ischemia in the distal field (watershed or border zone) in the region of lowest perfusion between its major branch vessels.

Regarding anoxic damage of the brain, Ames and Nesbett have studied the rabbit retina in an immersion chamber in which O2 and various substrates could be altered directly rather than through the vasculature. They found that cells could withstand complete absence of O2 for 20 min. After 30 min of anoxia, there was irreversible damage, reflected by an inability of the tissue to utilize glucose and to synthesize protein. Hypoglycemia further reduced the tolerance to hypoxia, whereas the tolerance could be increased by reducing the energy requirements of cells (increasing magnesium in the medium). Ames postulated that the long period of tolerance of retinal neurons to complete anoxia in vitro, in comparison to that in vivo, is related to what he called the no-reflow phenomenon (swelling of capillary endothelial cells, which prevents the restoration of circulation), as mentioned earlier. Body temperature is yet another important factor in determining the extent of infarction. A reduction of even 2 to 3°C (3.6 to 5.4°F) reduces the metabolic requirements of neurons and increases their tolerance to hypoxia by 25 to 30 percent.

These biochemical, cellular, and CBF findings enable one to conceptualize maneuvers for restoring blood flow within the marginally hypoperfused zone and salvaging brain tissue, particularly since under conditions of partial ischemia, cerebral tissue may survive for periods of 5 to 6 h or even longer.

NEUROVASCULAR SYNDROMES

The clinical picture that results from an occlusion of any one artery differs in minor ways from one patient to another, but there is sufficient uniformity to justify the assignment of a typical syndrome to each of the major arteries and their branches. The following descriptions apply particularly to the clinical effects of ischemia and infarction due to embolism and thrombosis. The identification by careful examination of highly specific neurovascular syndromes is one of cardinal skills of the clinical neurologist. Although hemorrhage within a specific vascular territory may give rise to many of the same effects, the total clinical picture is different because it usually involves regions supplied by more than one artery and, by its deep extension and pressure effects, causes secondary features of headache, vomiting, and hypertension as well as a series of falsely localizing signs, as described in Chaps. 17 and 31.

The Carotid Artery

The carotid system consists of three major arteries—the common carotid, internal carotid, and external carotid. As indicated in Fig. 34-2, the right common carotid artery arises at the level of the sternoclavicular notch from the innominate (brachiocephalic) artery, and the left common carotid comes directly from the aortic arch. The common carotids ascend in the neck to the C4 level, just below the angle of the jaw, where each divides into external and internal branches (sometimes the bifurcation is slightly above or below this point).

Common carotid occlusion accounts for less than 1 percent of cases of carotid artery syndrome—the remainder being due to disease of the internal carotid artery itself. Nevertheless, the common carotid can be occluded by an atheromatous plaque at its origin, more often on the left side. Atherosclerotic stenosis or occlusion of the midportion of the common carotid may also occur years after radiation therapy for laryngeal or other head and neck cancer. If the bifurcation is patent, few if any symptoms may result, in some cases because retrograde flow from the external carotid maintains internal carotid flow and perfusion of the brain.

Because the syndromes caused by common carotid occlusion are identical to those of its internal branch, the remainder of this discussion is concerned with disease of the internal carotid artery. The territory supplied by this vessel and its main branches is shown in Figs. 34-4, 34-5, and 34-6. The clinical manifestations of atherothrombotic disease of this artery are among the most variable of any cerebrovascular syndrome. Unlike other cerebral vessels, the internal carotid artery is not an end vessel. In most individuals it is in continuity with the vessels of the circle of Willis and those of the orbit, and no part of the brain is completely dependent on it. Therefore occlusion, which occurs most frequently in the first part of the internal carotid artery (immediately beyond the carotid bifurcation), is often silent (30 to 40 percent of cases).

There are two mechanisms by which strokes arise from atherosclerosis and superimposed thrombotic occlusion of the internal carotid artery. (We use the terms "atherothrombotic" and "atherothrombosis" here and in subsequent sections of the chapter to indicate this common mechanism of local stenosis, which leads to occlusion of the proximal parts of cerebral vessels or at their origins in the thorax and neck; see page 686). First, occlusion of the carotid may give rise to an embolus that passes distally in the territory of its tributary vessels, downstream from the internal carotid artery (middle and anterior cerebral arteries and their branches, as described further on). This has been termed "artery-to-artery embolism." Second, and less often, occlusion of the carotid artery may lead to ischemia in the distal field (watershed or border zone) in the region of lowest perfusion between its major branch vessels.
Figure 34-4. Diagram of a cerebral hemisphere, lateral aspect, showing the branches and distribution of the middle cerebral artery and the principal regions of cerebral localization. Below is a list of the clinical manifestations of infarction in the territory of this artery and the corresponding regions of cerebral damage.

</table>
Failure of distal perfusion may involve all or part of the middle cerebral territory; when the anterior communicating artery is very small, the ipsilateral anterior cerebral territory is affected as well. In extreme instances where the circle of Willis provides no communication to the side of an occluded carotid artery, thus isolating the hemisphere from other blood flow, massive infarction involving the anterior two-thirds or all of the cerebral hemisphere, including the basal ganglia, may result. If the two anterior cerebral arteries arise from a common stem on one side, infarction may occur in the territories of both vessels. The territory supplied by the posterior cerebral artery will also be included when this vessel is supplied by the internal carotid rather than the basilar artery (an occasional configuration that is a residual fetal configuration of the origin of the posterior cerebral artery).

If one internal carotid artery was occluded at an earlier time, occlusion of the other may cause bilateral cerebral infarction. The clinical effects in such cases may include coma with quadriplegia and continuous horizontal “metronomic” conjugate eye movements. Occlusion of the intracranial portion of the internal carotid artery—for example by an embolus to its distal part—produces a clinical picture like that of middle cerebral artery occlusion: contralateral hemiplegia, hemihypesthesia, and aphasia (with involvement of the dominant hemisphere). When the anterior cerebral territory is included, some or all of the clinical features of the latter will be added (see further on). Patients with such large infarctions are usually immediately drowsy or stuporous because of an ill-defined effect on the reticular activating system.

Headache—located as a rule, above the eyebrow—may occur with thrombosis or embolism of the carotid artery, but cranial pain is not invariable. The headache sometimes associated with occlusion of the middle cerebral artery tends to be more lateral, at the temple; that of posterior cerebral occlusion is in or behind the eye.

When the circulation of one carotid artery has been incompletely compromised, reducing blood flow in both the middle and anterior cerebral territories, the zone of maximal ischemia lies between the two vascular territories (“cortical watershed”) or, alternatively, in the deep portions of the hemisphere, between the territories of the lenticulostriate branches and the penetrating vessels from the convexity (“internal or deep watershed”). The infarction in the first instance occupies a region in the high parietal and frontal cortex and subcortical white matter. Its size depends upon the adequacy of collateral vessels. The weakness that results tends to involve the shoulder and hip more than the hand and face. With long-standing carotid stenosis, the cortical watershed zone tends to shift downward toward the perisylvian portions of the middle cerebral artery territory, even to the extent of affecting facial movement or causing a motor aphasia. The frequent sparing of the posterior part of the hemisphere is reflected in the low incidence of Wernicke types of aphasia and of homonymous hemianopia. With impaired perfusion of the so-called internal watershed, infarctions of varying size are situated in the subfrontal and subparietal portions of the centrum semiovale.

The situation is somewhat different in cases of circulatory collapse, usually from cardiac arrest, in which perfusion fails not only in the watershed areas between the middle and anterior cerebral arteries but also between the middle and posterior cerebral arteries. The infarction is then situated within a zone that extends as a sickle-shaped strip of variable width from the cortical convexity of the frontal lobe, through the high parietal lobe, to the occipitoparietal junction. Deeper infarctions also occur, but they more often take the form of contiguous extensions of the cortical infarction into the subjacent white matter. Also there may appear to be two or more separate infarctions after hypoperfusion states, but these turn out to be radiographically visible portions of a larger border-zone lesion.

The internal carotid artery nourishes the optic nerve and retina as well as the brain. For this reason, transient monocular blindness occurs prior to the onset of stroke in 10 to 25 percent of cases of symptomatic carotid occlusion. Yet central retinal artery ischemia is a relatively rare manifestation of carotid artery occlusion, presumably because of efficient collateral supply in the globe.

Whereas most cerebral arteries can be evaluated only indirectly by bedside techniques, more direct clinical means are available for the evaluation of the common and internal carotid arteries.

**Figure 34-5.** Diagram of a cerebral hemisphere, coronal section, showing the territories of the major cerebral vessels.
in the neck. With severe atherosclerotic stenosis at the level of the carotid sinus, with or without a superimposed thrombus, auscultation frequently discloses a bruit, best heard with the bell of the stethoscope held against the skin just tightly enough to create a seal (excessive pressure creates a diaphragm of the skin and filters the low-pitched frequencies that are typical of the bruit of carotid stenosis). Occasionally a bruit is due to stenosis at the origin of the external carotid artery or is a radiated murmur from the aortic valve and can then be misleading. If the bruit is loudest at the angle of the jaw, the stenosis usually lies at the proximal internal carotid; if heard lower in the neck, it is in the common carotid or subclavian artery. Rarely, stenosis in vertebral arteries or vascular malforma-

tions at the base of the brain may produce bruits heard posteriorly in the neck.

The duration and quality of the bruit are relevant—bruits that extend into diastole and are high-pitched are almost invariably associated with a tight stenosis (lumen < 1.5 mm). An additional though infrequent sign of carotid occlusion is the presence of a bruit over the opposite carotid artery, heard best by placing the bell of the stethoscope over the eyeball (ocular bruit). As pointed out by Pessin and colleagues (1983), this murmur is often due to augmented circulation through the patent vessel but there are as many instances in our experience when a bruit over the eye instead reflects a stenosis in the intracranial portion of the carotid artery on

*Note: Hemianopia does not occur; transcortical aphasia occurs rarely (page 423).*
that side. Pulsation may be palpably reduced or absent in the common carotid artery in the neck, in the external carotid artery in front of the ear, and in the internal carotid artery in the lateral wall of the pharynx, but these are among the least dependable signs of carotid disease and too vigorous compression risks dislodging plaque material. Also, in the presence of a unilateral internal carotid occlusion, compression of the normal common carotid should be avoided because it may precipitate neurologic symptoms.

Central retinal artery pressure is reduced on the side of a carotid occlusion or severe stenosis; this can be appreciated by gentle pressure on the globe while viewing the vessels emanating from the optic nerve head. A diastolic retinal pressure (determined by ophthalmicodynamometry) of less than 20 mmHg usually means that the common or internal carotid artery is occluded. These and other tests for assessing carotid flow have been largely supplanted by ultrasound insonation and MRI imaging of the carotid artery, but retinal examination remains highly valuable in that it may demonstrate emboli within retinal arteries, either shiny white or reddish in appearance; this is another important sign of carotid disease (crystalline cholesterol is sloughed from an atheromatous ulcer).

Additional signs of carotid occlusion include pulseless arms (as in Takayasu disease, see page 732); faintness on arising from the horizontal position or recurrent loss of consciousness when walking; headache and sometimes ocular, retro-orbital, and neck pain; transient blindness, either unilateral or bilateral; unilateral visual loss or dimness of vision with exercise, after exposure to bright light, or on assuming an upright position; retinal atrophy and pigmentation; atrophy of the iris; heterochromia of the iris (differing coloration on the two sides is a sign of carotid occlusion early in life); leukomas (corneal scars); peripapillary arteriovenous anastomoses in the retinae; optic atrophy; and claudication of jaw muscles.

The cardinal clinical sign of stenoses, ulcerations, and dissec-
tions of the internal carotid artery near its origin from the common carotid artery are TIAs. It is a subject of debate whether these are the result of fibrin platelet emboli or a reduction in blood flow. TIAs are discussed further on, but here it can be stated that TIAs and severe stenosis of the vessel represents an important risk factor for stroke.

Middle Cerebral Artery (MCA)

This artery has superficial and deep hemispheric branches. Through its cortical branches, it supplies the lateral (convexity) part of the cerebral hemisphere (Fig. 34-4). Its cortical territory encompasses (1) cortex and white matter of the lateral and inferior parts of the frontal lobe—including motor areas 4 and 6, contraversive centers for lateral gaze—and motor speech area of Broca (dominant hemisphere); (2) cortex and white matter of the parietal lobe, including the sensory cortex and the angular and supramarginal convolutions; and (3) superior parts of the temporal lobe and insula, including the sensory language areas of Wernicke. The deep penetrating or lenticulostriate branches of the middle cerebral artery supply the putamen, part of the head and body of the caudate nucleus, the outer globus pallidus, the posterior limb of the internal capsule, and the corona radiata (Fig. 34-5). The size of both the middle cerebral artery and the territory that it supplies is larger than those of the anterior and posterior cerebral arteries.

MCA Stem (M1) Occlusion The middle cerebral artery may be occluded in its stem (the term M1 is used by radiologists to denote this portion of the vessel), the portion that is distal to its origin at the distal internal carotid and proximal to its bifurcation. An occlusion here blocks the flow in the small deep penetrating vessels as well as in superficial cortical branches; alternatively, an occlusion at the distal end of the stem blocks the orifices of the divisions of the artery in the sylvian sulcus but leaves unaffected the more proximal deep penetrating vessels. The picture of total occlusion of the stem is one of contralateral hemiplegia (face, arm, and leg), hemianesthesia, and homonymous hemianopia (due to infarction of the lateral geniculate body), with deviation of the head and eyes toward the side of the lesion; in addition, there is a variable but usually global aphasia with left hemispheric lesions and anosognosia and amorphosynthesis with a right-sided ones (see Chap. 22). In the beginning, the patient may be dull or stuporous because of an ill-defined effect of widespread paralysis of neurologic function. Once fully established, the motor, sensory, and language deficits remain static or improve very little as months and years pass. If the patient is globally aphasic for a prolonged period of time, he seldom ever again communicates effectively (see Chap. 23 on the aphasic disorders). Occlusion of branches of the middle cerebral artery gives rise to only parts of the symptom complex. If there are adequate collateral vessels over the surface of the hemisphere, only those component of the stroke referable to the deep structures are evident (mainly hemiplegia encompassing the contralateral limbs and face, as discussed below, under “Deep MCA Territory Occlusion”), the cortical elements then being absent or mild (aphasia, agnosia, etc.).

Occlusion of the stem of the middle cerebral artery by a thrombus, contrary to conventional teaching, is relatively infrequent (less than 10 percent of middle cerebral artery occlusions in our experience); cerebral embolism is a more common cause. Pathologic studies over the years have shown that most carotid occlusions are thrombotic, whereas most middle cerebral artery occlusions are embolic (Fisher, 1975; Caplan, 1989). The emboli tend to lodge in the stem or, more often, drift into superficial cortical branches; not more than 1 in 20 will enter deep penetrating branches that originate in the stem. The middle cerebral artery may, however, become stenotic from atherosclerosis. In several series of such cases, the permanent stroke was preceded by TIAs, producing a picture resembling that of carotid stenosis (see Day; Caplan).

MCA Branch (Superior and Inferior Division) Occlusion

Superior Division An embolus entering the middle cerebral artery most often lodges in one of its two main branches, the superior division (supplying the rolandic and prerolandic areas) or the inferior division (supplying the lateral temporal and inferior parietal lobes). Major infarction in the territory of the superior division causes a dense sensorimotor deficit in the contralateral face, arm, and, to a lesser extent, leg as well as ipsilateral deviation of the head and eyes; i.e., it mimics the syndrome of stem occlusion except that the foot is spared and the leg is less involved than the arm and face (“brachiofacial paralysis”); there is no impairment of alertness. If the occlusion is lasting (not merely transient ischemia with disintegration of the embolus), there will be slow improvement; after a few months, the patient will be able to walk with a spastic leg, while the motor deficits of the arm and face remain. The sensory deficit may be profound, resembling that of a thalamic infarct (pseudothalamic syndrome of Foix), but more often it is less severe than the motor deficit, taking the form of stereoneesthesi, agraphasia, impaired position sense, tactile localization, and two-point discrimination as well as variable changes in touch, pain,
and temperature sense. With left-sided lesions there is initially a global aphasia, which changes gradually to a predominantly motor (Broca) aphasia, with improvement in comprehension of spoken and written words and the emergence of an effortful, hesitant, grammatically simplified, and dysmelodic speech (Chap. 23); or there is a Broca aphasia from the outset.

Embolic occlusion limited to one of the branches of the superior division, perhaps the most common stroke seen in clinical practice, produces a more circumscribed infarct that further fractionates the above described syndrome. With occlusion of the ascending frontal branch, the motor deficit is limited to the face and arm with little or no affection of the leg, and the latter, if weakened at all, soon improves; with left-sided lesions, there is disfluent and agrammatic speech, with normal comprehension (page 418). Embolic occlusion of the Rolandic branches results in sensorimotor paresis with severe dysarthria but little evidence of aphasia. A cortical-subcortical branch occlusion may give rise to a brachial monoplegia. Embolic occlusion of ascending parietal and other posterior branches of the superior division may cause no sensorimotor deficit but only a conduction aphasia (page 421) and bilateral ideomotor apraxia. There are many other limited stroke syndromes or combinations of the aforementioned syndromes relating to small regions of damage in the frontal, parietal, or temporal lobes. Most of these are discussed in Chap. 22, on lesions in particular parts of the cerebrum. Improvement can be expected within a few weeks to months but often some remnant of the original problem remains in place. As indicated earlier, the distal territory of the middle cerebral artery may also be rendered ischemic by failure of the systemic circulation, especially if the carotid artery is stenotic; this territory of the middle cerebral artery may also be rendered ischemic by failure of the systemic circulation, especially if the carotid artery is stenotic; this may simulate embolic branch occlusions.

**Inferior Division** Occlusion of the inferior division of the middle cerebral artery is slightly less frequent than occlusion of the superior one, but again is nearly always due to embolism. The usual result in left-sided lesions is a Wernicke aphasia, which generally remains static for days or weeks, or a month or two, after which some improvement can be expected (page 419). In less extensive infarcts from branch occlusions (superior parietal, angular, or posterior temporal), the deficit in comprehension of spoken and written language may be especially severe. Again, after a few months, the deficits usually improve, often to the point where they are evident only in self-generated efforts to read and copy visually presented words or phrases. With either right- or left-hemispheric lesions, there is usually a superior quadrananopia or homonymous hemianopia and, with right-sided ones, a left visual neglect and other signs of amorphosynthesis; rarely, an agitated confusional state, presumably from temporal lobe damage, may be a prominent feature of dominant hemispheral lesions and sometimes of nondominant ones.

Deep MCA (“MCA Stem,” M1) Territory Occlusion (Striato-capsular Infarction) A number of interesting syndromes occur with deep lesions in the territory of the penetrating vessels of the middle cerebral artery (Figs. 34-5 and 34-7). Most are attributable to emboli to the stem of the middle cerebral artery, although imaging studies show a patent vessel in half of the cases; a few are presumably atherothrombotic. There have been few adequate pathologic studies. Although centered in the deep white matter, most of these lesions are fragments of the cortical-subcortical stroke patterns described above. The most common type in our experience has been a large striatocapsular infarction, similar to that described by Weller and colleagues. All of their patients had some degree of hemiparesis and one-fifth had aphasia or hemineglect.

Aphasia, when it occurs, tends to be a limited form of the Broca type and, in our experience, has been short-lived. With deep small strokes, we have most often encountered incomplete motor syndromes affecting only the arm and hand, without language disturbance or neglect; these are quite difficult to differentiate from small embolic cortical strokes. The lesions in the corona radiata are larger than typical lacunes (see further on) but probably have a similar pathophysiology.

Foix and Levy, who described the clinical effects of deep capsular-basal ganglionic lesions and of more superficial cortical-subcortical ones, found few important differences in the degree and pattern of the hemiplegia and sensory disorder. Homonymous hemianopia may occur with posterior capsular lesions, but it must be distinguished from visual hemineglect of contralateral space. Bilateral cerebral infarctions involving mainly the insular-perisylvian (anterior opercular) regions manifest themselves by a facio-glosso-pharyngo-masticatory diplegia (anarthria without aphasia; see Mao et al).

**Anterior Cerebral Artery**

This artery, through its cortical branches, supplies the anterior three-quarters of the medial surface of the frontal lobe, including its medial-orbital surface, the frontal pole, a strip of the lateral surface of the cerebral hemisphere along the superior border, and the anterior four-fifths of the corpus callosum. Deep branches, arising near the circle of Willis (proximal or distal to the anterior communicating artery), supply the anterior limb of the internal capsule, the inferior part of the head of the caudate nucleus, and the anterior part of the globus pallidus (Figs. 34-5, 34-6, and 34-7). The largest of these deep branches is the artery of Heubner.

The clinical picture will depend on the location and size of the infarct, which, in turn, relates to the site of the occlusion, the pattern of the circle of Willis, and the other ischemia-modifying factors mentioned earlier. Well-studied cases of infarction in the territory of the anterior cerebral artery are not numerous; hence the syndromes have not been completely elucidated (see Brust and also Bogousslavsky and Regli for a review of the literature and a description of developmental abnormalities of the artery).

Occlusion of the stem of the anterior cerebral artery, proximal to its connection with the anterior communicating artery (the A1 segment, in neuroradiologic parlance), is usually well tolerated, since adequate collateral flow will come from the artery of the opposite side. Maximal disturbance occurs when both arteries arise from one anterior cerebral stem, in which case occlusion of the stem will cause infarction of the anterior and medial parts of both cerebral hemispheres and result in paraplegia, incontinence, abulia, and motor aphasic symptoms, and frontal lobe personality changes (Chap. 22). Occlusion of the anterior cerebral arteries is usually embolic, but atherothrombotic lesions are known and surgical instances have been described (occlusion with operations on anterior communicating aneurysms).

Complete infarction due to occlusion of one anterior cerebral artery distal to the anterior communicating artery (A2 segment) results in a sensorimotor deficit of the opposite foot and leg and, to a lesser degree, of the shoulder and arm, with sparing of the hand and face. The motor disorder is more pronounced in the foot and leg than in the hip and thigh. Sensory loss, when it occurs, is mainly of the discriminative modalities and is mild or absent in some cases. The head and eyes may deviate to the side of the lesion. Urinary incontinence and a contralateral grasp reflex and paratonic
rigidity (gegenhalten) may be evident. With a left-sided occlusion, there may be a sympathetic apraxia of the left arm and leg or involuntary misdirected movements of the left arm (alien arm or hand). Also, transcortical motor aphasia (page 423) may occur with occlusions of Heubner’s branch of the left anterior cerebral artery. Alexander and Schmitt cite cases in which a right hemiplegia (predominant in the leg) with grasping and groping responses of the right hand and buccofacial apraxia are accompanied by a diminution or absence of spontaneous speech, agraphia, labored telegraphic speech, and a limited ability to name objects and compose word lists but with a striking preservation of the ability to repeat spoken and written sentences (i.e., transcortical motor aphasia). Disorders of behavior that may be overlooked are abulia, presenting as slowness and lack of spontaneity in all reactions, muteness or a tendency to speak in whispers, and distractibility. Branch occlusions of the anterior cerebral artery produce only fragments of the total syndrome, usually a spastic weakness or corticosensory loss in the opposite foot and leg.

With occlusion of penetrating branches of the anterior cerebral artery on one or both sides, the anterior limb of the internal capsule and caudate are usually involved. In a series of 18 cases of unilateral caudate region infarcts collected by Caplan and associates, a transient hemiparesis was present in 13. Dysarthria and either abulia or agitation and hyperactivity were also common. Stuttering and language difficulty occurred with two of the left-sided lesions and visuospatial neglect with three of the right-sided ones. To what extent these symptoms were due to a disturbance of neighboring structures is difficult to determine. With bilateral caudate infarctions, a syndrome of inattentiveness, abulia, forgetfulness, and sometimes agitation and psychosis was observed. Transitory choreoathetosis and other dyskineties have also been attributed to ischemia of basal ganglia, occurring sometimes under conditions of prolonged standing and exercise (Caplan and Sergay; Margolin and Marsden).

**Anterior Choroidal Artery**

This is a long, narrow artery that springs from the internal carotid, just above the origin of the posterior communicating artery. It supplies the internal segment of the globus pallidus and posterior limb of the internal capsule and various contiguous structures, including (in most patients) the optic tract (Fig. 34-5); then it penetrates the temporal horn of the lateral ventricle, where it supplies the choroid plexus and anastomoses with the posterior choroidal artery.

Only a few complete clinicopathologic studies have been made of the syndrome caused by occlusion of this artery. It was found by Fox and colleagues to consist of contralateral hemiplegia, hemihypестhesia, and homonymous hemianopia due to involvement of the posterior limb of the internal capsule and white matter posterolateral to it, through which the geniculocalcarine tract passes. Cognitive and language functions are notably spared in most cases. This combination of extensive motor, sensory, and visual impairment in an individual with well-preserved language and cognition distinguishes this stroke syndrome from the more common syndromes involving the major cerebral arteries. Decroix and colleagues reported 16 cases (identified by CT) in which the lesion appeared to lie in the vascular territory of this artery. In most of their cases the clinical syndrome fell short of what was expected on anatomic grounds. With right-sided lesions, there may be a left spatial neglect and constructional apraxia; slight disorders of speech and language may accompany left-sided lesions. Hupperts and colleagues have discussed the controversy regarding the effects of occlusion of the anterior choroidal artery and in particular the variability of its supply to the posterior paraventricular area of the corona radiata and adjacent regions. They concluded, also from a survey of CT scans, that there was no uniform syndrome attributable to occlusion of this vessel and that in most cases its territory of supply was overlapped by small surrounding vessels. Of course, in both these studies, the lesions may have extended beyond the territory of this artery, since postmortem confirmation was lacking. It should be remembered that for a time, in order to abolish the tremor and rigidity of unilateral Parkinson disease, the anterior choroidal artery was being surgically ligated without these other effects having been produced.

**Vertebrobasilar and Posterior Cerebral Arteries**

**Posterior Cerebral Artery**

In about 70 percent of persons, both posterior cerebral arteries are formed by the bifurcation of the basilar artery, and only thin posterior communicating arteries join this system to the internal carotid arteries. In 20 to 25 percent, one posterior cerebral artery arises from the basilar in the usual way, but the other arises from the internal carotid, a so-called persistent fetal circulation; in the remainder, both arise from the corresponding carotids.

The configuration and branches of the proximal segment of the posterior cerebral artery (P1 segment) are illustrated in Figs. 34-6, 34-8, and 34-9. The interpeduncular branches, which arise...

just above the basilar bifurcation, supply the red nuclei, the substantia nigra bilaterally, medial parts of the cerebral peduncles, oculomotor and trochlear nuclei and nerves, reticular substance of the upper brainstem, decussation of the brachia conjunctivae (superior cerebellar peduncles), medial longitudinal fasciculi, and medial lemnisci. The portion of the posterior cerebral artery giving rise to the interpeduncular branches (the portion between the bifurcation of the basilar artery and the ostium of the posterior communicating artery) is also referred to as the mesencephalic artery or the basilar communicating artery.

The thalamoperforate branches (also called paramedian thalamic arteries) arise slightly more distally, near the junction of the posterior cerebral and posterior communicating arteries (P2 segment of the artery) and supply the inferior, medial, and anterior parts of the thalamus. As pointed out by Percheron (whose name is often applied to the largest of these vessels), the arterial configuration of the thalamoperforate arteries varies considerably: in some cases they arise symmetrically, one from each side; in others, both arteries arise from the same posterior cerebral stem, either separately or by a common trunk, which then bifurcates. In the latter case, one posterior cerebral stem supplies the medial thalamic territories on both sides, and an occlusion of this artery or one common paramedian trunk produces a bilateral butterfly-shaped lesion in the medial parts of the diencephalon. The thalamogeniculate branches arise still more distally, opposite the lateral geniculate body, and supply the geniculate body and the central and posterior parts of the thalamus. Medial branches from the posterior cerebral, as it encircles the midbrain, supply the lateral part of the cerebral peduncle, lateral tegmentum and corpora quadrigemina, and pineal gland. Posterior choroidal branches run to the posterosegmental thalamic, choroid plexus, posterior parts of the hippocampus, and psalterium (decussation of fornices).

The terminal or cortical branches of the posterior cerebral artery supply the inferomedial part of the temporal lobe and the medial occipital lobe, including the lingula, cuneus, precuneus, and visual Brodmann’s areas 17, 18, and 19 (see Figs. 34-6, 34-8, and 34-9).

Occlusion of the posterior cerebral artery produces a greater variety of clinical effects than occlusion of any other artery because both the upper brainstem, which is crowded with important structures, and the inferomedial parts of the temporal and occipital lobes lie within its domain. Obviously, the site of the occlusion and the arrangement of the circle of Willis will in large measure determine the location and extent of the resulting infarct. For example, occlusion proximal to the posterior communicating artery may be asymptomatic or have only transitory effects if the collateral flow is adequate from the opposite posterior cerebral vessel (Fig. 34-8; see also Fig. 34-9). Even distal to the posterior communicating artery, an occlusion may cause relatively little damage if the collateral flow through border-zone collaterals from anterior and middle cerebral arteries is sufficient.

In the series of posterior cerebral artery strokes studied by Milandre and coworkers, the causes were in general similar to those of strokes in other vascular territories except that there was a surprisingly high incidence of atherosclerotic occlusion (35 patients) in contrast to cardioembolic types (15 patients). Two of their stroke cases were attributed to migraine. Our experience has differed in that the proportion of presumed embolic occlusions has been far greater than that of other causes.

For convenience of exposition, it is helpful to divide the posterior cerebral artery syndromes into three groups: (1) anterior and proximal (involving interpeduncular, thalamic perforant, and thalamogeniculate branches), (2) cortical (inferior temporal and mediodorsal thalamic, and (3) bilateral.

**Anterior and Proximal Syndromes (See Figs. 34-9 and 34-10.)**

The thalamic syndrome of Déjerine and Roussy (page 141) follows infarction of the sensory relay nuclei in the thalamus, the result of occlusion of thalamogeniculate branches. There is both a deep and cutaneous sensory loss, usually severe in degree, of the opposite side of the body, including the trunk and face, sometimes accompanied by a transitory hemiparesis. A homonymous hemianopia may be conjoined. In some instances there is a dissociated sensory loss—pain and thermal sensation being more affected than touch, vibration, and position—or only one part of the body may be anesthetic. But again, the characteristic feature is sensory loss that includes the entire hemibody up to the midline. After an interval, sensation begins to return, and the patient may then develop pain, paresthesia, and hyperpathia in the affected parts. The painful paresthetic syndrome may persist for years. There may also be distortion of taste, athetotic posturing of the hand, and alteration of mood. Mania and depression have occasionally been observed with infarction of the diencephalon and adjacent structures, but the data are usually incomplete.

**Central midbrain and subthalamic syndromes** are due to occlusion of the interpeduncular branches of the posterior cerebral artery. The clinical syndromes include palsies of vertical gaze, stupor, or coma. Syndromes of the paramedian arteries, including the proximal posterior cerebral artery, have as their main feature a third nerve palsy combined with contralateral hemiplegia (Weber syndrome), contralateral ataxic tremor (Benedikt syndrome), or ataxia and hemiparesis (Claude syndrome) as summarized in Table 34-3, page 681.

**Anteromedial-inferior thalamic syndromes** follow occlusion of the thalamoperforant branches. Here the most common effect is an extrapyramidal movement disorder (hemiballismus or hemichorea-thetosis or less often, asterixis). Deep sensory loss, hemiataxia, or tremor may be added in various combinations. Hemiballismus is usually due to occlusion of a small branch to the subthalamic nucleus (of Luys) or its connections with the pallidum. Occlusion of the paramedian thalamic branch(es) to the mediodorsal thalamic nuclei or to the dominant (left) mediodorsal thalamic nucleus is a recognized

substrate of the vascular amnesic (Korsakoff) syndrome; this simulates infarction of the hippocampi from occlusion of the medial temporal branch of the posterior cerebral artery as noted below.

**Unilateral Cortical Syndromes** Occlusion of branches to the temporal and occipital lobes gives rise to a homonymous hemianopia as a result of involvement of the primary visual receptive areas (calcarine or striate cortex) or of the converging geniculo-calcarine fibers. It may be incomplete and then involves the upper quadrants of the visual fields more than the lower ones (see Chap. 13). Macular or central vision may be spared because of collateralization of the occipital pole from distal branches of the middle (or anterior) cerebral arteries. There may be visual hallucinations in the blind parts of the visual fields (Cogan) or metamorphopsia (Brust and Behrens).

Posterior cortical infarcts of the dominant hemisphere cause alexia (with or without agraphia), anomia (amnesic aphasia), a variety of visual agnosias, and rarely some degree of impaired memory. The anomias (dysnomias) are most severe for colors, but the naming of other visually presented material such as pictures, musical notes, mathematical symbols, and manipulable objects may also be impaired. The patient may treat objects as familiar—that is, describe their functions and use them correctly—but be unable to name them. Color dysnomia and amnesic aphasia are more often present in this syndrome than is alexia. The defect in retentive memory is of varying severity and may or may not improve with the passage of time. These syndromes are described in Chaps. 22 and 23.

A complete proximal arterial occlusion leads to a syndrome that combines cortical and anterior-proximal syndromes in part or totally. The vascular lesion may be either an embolus or an atherosclerotic thrombus.

**Bilateral Cortical Syndromes** These occur as a result of successive infarctions or from a single embolic or thrombotic occlusion of the upper basilar artery, especially if the posterior communicating arteries are unusually small.

Bilateral lesions of the occipital lobes, if extensive, cause total “cortical blindness,” i.e., a bilateral homonymous hemianopia, sometimes accompanied by unusual visual hallucinations. The pupillary reflexes are preserved, and the optic discs appear normal. Sometimes the patient is unaware of being blind and may deny it even when it is pointed out to him (Anton syndrome). More frequently the lesions are incomplete, and a sector of the visual fields, usually on one side, remains intact. When the intact remnant is small, vision may fluctuate from moment to moment as the patient attempts to capture the image in the island of intact vision, in which case hysteria is incorrectly inferred. The Balint syndrome (page 406) is another effect of bilateral occipitoparietal border-zone lesions. In bilateral lesions confined to the occipital poles, there may be a loss of central vision only (homonymous central scotomas).

With more anteriorly placed lesions of the occipital pole, there may be homonymous paracentral scotomas, or the occipital poles may be spared, leaving the patient with only central vision. Horizontal or altitudinal field defects are usually due to similar restricted lesions affecting the upper or lower banks of the calcarine sulci.

With bilateral lesions that involve the inferomedial portions of the temporal lobes, the impairment of memory may be severe, causing the Korsakoff amnesic state. In several of our patients, a solely left-sided infarction of the inferomedial temporal lobe impaired retentive memory. These amnesic states and their accompaniments are fully described in Chaps. 21 and 22. Bilateral mesiotemporal-occipital lesions also cause a lack of recognition of faces (prosopagnosia). These and other effects of temporal and occipital lesions are discussed in Chaps. 13 and 22.

**Vertebral Artery** The vertebral arteries are the chief arteries of the medulla; each supplies the lower three-fourths of the pyramid, the medial lemniscus, all or nearly all of the retro-olivary (lateral medullary) region, the restiform body, and the postero-inferior part of the cerebellar hemisphere (Figs. 34-11 and 34-12). The relative sizes of the vertebral arteries vary considerably, and in approximately 10 percent of cases, one vessel is so small that the other is essentially the only artery of supply to the brainstem. In the latter
cases, if there is no collateral flow from the carotid system via the circle of Willis, occlusion of the one functional vertebral artery is equivalent to occlusion of the basilar artery (see below). The posteroinferior cerebellar artery (PICA) is usually a branch of the vertebral artery but can have a common origin with the anteroinferior cerebellar artery (AICA) from the basilar artery. It is necessary to keep these anatomic variations in mind in considering the effects of vertebral artery occlusion.

The vertebral arteries are most often occluded by atherothrombosis in their intracranial portion. Since the vertebral arteries have a long extracranial course and pass through the transverse processes of C6 to C1 vertebrae before entering the cranial cavity, one might expect them to be subject to trauma, spondylotic compression, and a variety of other vertebral diseases. With the exception of arterial dissection, in our experience this happens only infrequently. We have not seen convincing examples of spondylotic occlusion but several have been reported. Extreme extension of the neck, as experienced by women who are having their hair washed in beauty salons, may give rise to transient symptoms in the territory of the vertebral artery.

Dissection of the vertebral artery is well described; it declares itself by cervico-occipital pain and deficits of brainstem function, usually bilateral. It may be precipitated by vigorous and protracted bouts of coughing or by trauma to the neck or head. Dissection of the extracranial vessels is discussed under “Dissection of the Cervical and Intracranial Vessels,” further on. Examples of “posterior circulation” stroke in children have been reported in association with odontoid hypoplasia and other atlantoaxial dislocations, causing the vertebral arteries to be stretched or kinked in their course through the transverse processes of C1-C2 (see Phillips et al).

The results of vertebral artery occlusion are quite variable. When there are two good-sized arteries, occlusion of one PICA may cause no recognizable symptoms and signs. If the occlusion of the vertebral artery is so situated as to block the branch supplying the lateral medulla and inferior cerebellum (PICA), a characteristic syndrome results with vertigo being a prominent symptom (see “Lateral Medullary Syndrome” below). If the subclavian artery is blocked proximal to the origin of the left vertebral artery, exercise of the arm on that side may draw blood from the right vertebral and basilar arteries, down the left vertebral and into the distal left subclavian artery—sometimes resulting in the symptoms of basilar insufficiency. This phenomenon, described in 1961 by Reivich and colleagues, was referred to by Fisher as the subclavian steal. Its most notable features are vertigo and sometimes other brainstem signs coupled with transient weakness on exercise of the left arm. There may also be headache and claudication or pain of the arm.

Less often, occlusion of the vertebral artery or one of its medial branches produces an infarct that involves the medullary pyramid, the medial lemniscus, and the emergent hypoglossal fibers; the resultant syndrome consists of a contralateral paralysis of arm and leg (with sparing of the face), contralateral loss of position and vibration sense, and ipsilateral paralysis and later atrophy of the tongue. This is the medial medullary syndrome (Fig. 34-13). A more limited lesion, from occlusion of one spinal artery arising from the vertebral artery, gives rise to a contralateral hemiplegia (rarely a quadriplegia) that spares the face. When the vertebral branch to the anterior spinal artery is blocked, flow from the other (corresponding) branch is usually sufficient to prevent infarction of the cervical cord, but we and others have described pyramidal infarction with hemiplegia that spares the face. Occlusion of a vertebral artery low in the neck is usually compensated by anastomotic flow to the upper part of the artery via the thyrocervical, deep cervical, and occipital arteries or reflux from the circle of Willis.

Lateral Medullary Syndrome Known also as the Wallenberg syndrome (who described a case in 1895), this common stroke is produced by infarction of a wedge of lateral medulla lying posterior to the inferior olivary nucleus (Fig. 34-13). The complete syndrome, as outlined by Fisher and colleagues (1961), comprises involvement of the vestibular nuclei (vertigo, nystagmus, oscillopsia, vomiting); spinthalamic tract (contralateral or, less often, ipsilateral impairment of pain and thermal sense over half the body); descending sympathetic tract (ipsilateral Horner syndrome—mio-

est infarction we have studied gave rise only to symptoms of lateropulsion and mild ipsilateral limb ataxia.

The eye signs of lateral medullary infarction may be difficult to interpret. Often there is a fragment of an internuclear ophthalmoplegia or a skew deviation (the globe on the affected side usually higher). Direction changing nystagmus (with different head positions) is said to be the most useful feature that distinguishes labyrinthine disease from brainstem forms of nystagmus, but infarction of the vestibular nucleus as part of the lateral medullary syndrome may also show this sign (see also Chap. 15).

The entire lateral medullary syndrome, one of the most striking in neurology, is almost always due to infarction, with only a small number of cases being the result of hemorrhage or tumor. Although it was traditionally attributed to occlusion in the course of the posterior inferior cerebellar artery (PICA), careful studies have shown that in 8 out of 10 cases it is the vertebral artery that is occluded by atherothrombosis; in the remainder, either the posterior inferior cerebellar artery or one of the lateral medullary arteries is occluded. Embolism is a less frequent cause. The inferior cerebellum is usually affected, causing vomiting, vertigo, and ataxia.

In recent years, we have become aware from our own patients that although most of those with lateral medullary infarction do well and have considerable recovery, sudden and unexpected death may occur from respiratory or cardiac arrest, sometimes even in the absence of cerebellar swelling or basilar artery thrombosis. Cases of this nature have been reviewed by Norving and Cronqvist. The related and important issue of cerebellar swelling after vertebral artery or PICA occlusion and the subsequent need for surgery is discussed under “Treatment of Cerebral Edema and Raised Intracranial Pressure,” later in the chapter.

Basilar Artery  The branches of the basilar artery may be instructively grouped as follows: (1) paramedian, 7 to 10 in number, supplying a wedge of pons on either side of the midline; (2) short circumferential, 5 to 7 in number, supplying the lateral two-thirds of the pons and the middle and superior cerebellar peduncles; (3) long circumferential, 2 on each side (the superior and anterior inferior cerebellar arteries), which run laterally around the pons to reach the cerebellar hemispheres (Figs. 34-11 and 34-12); and (4) several paramedian (interpeduncular) branches at the bifurcation of the basilar artery and origins of the posterior cerebral arteries supplying the high midbrain and medial subthalamic regions. These interpeduncular and other short proximal branches of the posterior cerebral artery have been described above.

The picture of basilar artery occlusion due to thrombosis may arise in several ways: (1) occlusion of the basilar artery itself, usually in the lower or middle third at the site of an atherosclerotic plaque and superimposed thrombosis; (2) occlusion of both vertebral arteries; and (3) occlusion of a single vertebral artery when it is the only one of adequate size. Also, thrombosis may involve a branch of the basilar artery rather than the trunk (basilar branch occlusion). When there is embolism, the clot usually lodges at the upper bifurcation of the basilar or in one of the posterior cerebral arteries, since the embolus, if it is small enough to pass through the vertebral artery, easily traverses the length of the basilar artery, which is of greater diameter than either vertebral artery. The syndrome of basilar artery occlusion, as delineated by Kubik and Adams, reflects the involvement of a large number of structures: corticospinal and corticobulbar tracts, cerebellum, middle and superior cerebellar peduncles, medial and lateral lemnisci, spinothalamic tracts, medial longitudinal fasciculi, pontine nuclei, vestibular and cochlear nuclei, descending hypothalamic sympathetic fibers, and the third through eighth cranial nerves (the nuclei and their segments within the brainstem).

The complete basilar syndrome comprises bilateral long tract signs (sensory and motor) with variable cerebellar, cranial nerve, and other segmental abnormalities of the brainstem. Often the patient is comatose because of ischemia of the high midbrain reticular activating system. Others are mute and quadriplegic but conscious, reflecting interruption of descending motor pathways in the base of the pons but sparing of the reticular activating system (“locked-in” syndrome; see page 305). Midbasilar disease may also cause coma if the posterior communicating arteries are inadequate to perfuse the distal basilar artery territory. In the presence of the full syndrome, it is usually not difficult to make the correct diagnosis. The aim should be, however, to recognize basilar insufficiency long before the stage of total deficit has been reached. The early manifestations (in the form of TIAs) occur in many combinations, described in detail further on (page 692).

**Basilar Branch Occlusion**  Occlusion of branches at the bifurcation (top) of the basilar artery results in a remarkable number of complex syndromes that include, in various combinations, somnolence or coma, memory defects, akinetic mutism, visual hallucinations, ptosis, disorders of ocular movement (convergence spasm, paralysis of vertical gaze, retraction nystagmus, pseudoabducens palsy, retraction of upper eyelids, skew deviation of the eyes), an agitated confusional state, and visual defects. These have been reviewed by Petit and coworkers and Castaigne and associates as paramedian thalamic, subthalamic, and midbrain infarction syndromes and by Caplan as the “top of the basilar” syndrome.

The main signs of occlusion of the superior cerebellar artery are ipsilateral cerebellar ataxia of the limbs (middle and/or superior cerebellar peduncles); nausea and vomiting; slurred speech; and loss of pain and thermal sensation over the opposite side of the body (spinothalamic tract). Partial deafness, static tremor of the ipsilateral upper extremity, an ipsilateral Horner syndrome, and palatal myoclonus have also been reported, but we have not seen these.

With occlusion of the anteroinferior cerebellar artery (AICA), the extent of the infarct is extremely variable, since the size of this artery and the territory it supplies vary inversely with the size and territory of supply of the posteroinferior cerebellar artery (PICA). The principal findings are vertigo, vomiting, nystagmus, tinnitus and sometimes unilateral deafness; facial weakness; ipsilateral cerebellar ataxia (inferior or middle cerebellar peduncle); an ipsilateral Horner syndrome and paresis of conjugate lateral gaze; and contralateral loss of pain and temperature sense of the arm, trunk, and leg (lateral spinothalamic tract). The tinnitus may be overwhelming, called “screaming” by some of our patients. If the occlusion is close to the origin of the artery, the corticospinal fibers may also be involved, producing a hemiplegia; if distal, there may be cochlear and labyrinthine infarction. Cerebellar swelling has not occurred in our cases or in the 20 collected by Amarenco and Hauw.

The most characteristic manifestation of all these branch or division brainstem infarcts is the “crossed” cranial nerve and long tract sensory or motor deficit. These crossed syndromes, which may involve cranial nerves III through XII, are listed in Table 34-3. Although the finding of bilateral neurologic signs strongly suggests brainstem involvement, it must be emphasized that in many instances of infarction within the basilar territory, the signs are lim-

and medial medullary. Figures 34-13 to 34-16, supplied by C. M.
ized are the full basilar, vertebral-PICA, posteroinferior cerebel-
region of the brain is not greatly facilitated by a knowledge of these
nonvascular diseases. The diagnosis of vascular disorders in this
ing" phenomena must be used to identify the exact site.

A myriad of proper names have been applied to the brainstem
syndromes, as noted in Tables 34-3 and 47-1 (page 1180). Most
of them were originally described in relation to tumors and other
nonvascular diseases. The diagnosis of vascular disorders in this
region of the brain is not greatly facilitated by a knowledge of these
eponymic syndromes; it is much more profitable to memorize the
anatomy of the brainstem. The principal syndromes to be recog-
ized are the full basilar, vertebral-PICA, posteroinferior cerebel-
lar, anteroinferior cerebellar, superior cerebellar, pontomedullary,
and medial medullary. Figures 34-13 to 34-16, supplied by C. M.
Fisher and used in all previous editions of this book, present both
medial and lateral syndromes at four levels of the medulla and
pons. Other syndromes can usually be identified as fragments or
“neighboring” phenomena must be used to identify the exact site.

Another feature of note is that it is not possible to distinguish
a hemiplegia of pontine origin from one of deep cerebral origin on
the basis of motor signs alone. In both, the face, arm, hand, leg,
and foot are affected. With brainstem lesions as with cerebral ones,
a flaccid paralysis gives way to spasticity after a few days or weeks,
and there is no satisfactory explanation for the variability in this
period of delay or for the occurrence in some cases of spasticity
from the onset of the stroke. There may also be a combined hemi-
paresis and ataxia of the limbs on the same side. Localization of
brainstem hemiplegia depends on coexisting neurologic signs.
With a hemiplegia of pontine origin, the eyes may deviate to the
side of the paralysis, i.e., the opposite of what occurs with supra-
tentorial lesions. The pattern of sensory disturbance may be helpful.
A dissociated sensory deficit over the ipsilateral face and contra-
lateral half of the body usually indicates a lesion in the lower brain-
stem, while a hemisensory loss including the face and involving
all modalities indicates a lesion in the upper brainstem, in the thal-
amus, or deep in the white matter of the parietal lobe. When po-
tion sense, two-point discrimination, and tactile localization are
affected relatively more than pain or thermal and tactile sense, a
cerebral lesion is suggested; the converse indicates a brainstem
localization. Bilaterality of both motor and sensory signs is almost
certain evidence that the lesion lies in the brainstem. When hemi-
plegia or hemiparesis and sensory loss are coextensive, the lesion
usually lies supratentorially. Additional manifestations that point
unequivocally to a brainstem site are rotational dizziness, diplopia,
cerebellar ataxia, a Horner syndrome, and deafness. The several
brainstem syndromes illustrate the important point that the cere-
bellar pathways, spinothalamic tract, trigeminal nucleus, and sym-
thetic fibers can be involved at different levels, and “neighboring”
phenomena must be used to identify the exact site.

If the lacuna lies in the territory of a lenticulostriate artery,
i.e., in the internal capsule or adjacent corona radiata, it causes a
pure motor hemiplegia involving the face, arm, hand, leg, and foot.
A lacuna situated in the ventral pons may cause an identical syn-
drome. Symptoms may be abrupt in onset or evolve over several
hours, but in some instances (10 of 34 cases, according to Weis-
berg) the neurologic deficit evolves stepwise and relatively slowly,
over as long a period as 2 to 3 days, thereby simulating a small
hemorrhage. CT scanning shows the lesions in about two-thirds of
cases if several days have passed, and MRI in almost all cases
within hours of the stroke Sometimes the motor disorder takes the
form of a more limited hemiplegia of the face and arm or arm and
leg, or a dysarthria with or without hemiplegia. Recovery, which
may begin within hours, days, or weeks, is sometimes nearly com-
plete, even in the face of a severe initial stroke. However, many
patients are left with some degree of clumsiness or slowness of
movement of the affected side.

Lacunar Syndromes
As one might surmise, small penetrating branches of the cerebral
arteries may become occluded, and the resulting infarcts may be
so small or so situated as to cause no symptoms whatsoever. As
the softened tissue is removed, it leaves a small cavity, or lacune.
Early in the twentieth century, Pierre Marie confirmed the occur-
rence of multiple deep small cavities of this type, first described
by Durant-Fardel in 1843. Marie referred to the condition as état
lacunaire. He distinguished these lesions from a fine loosening of
tissue around thickened vessels that enter the anterior and posterior
perforated spaces, a change to which he gave the name état criblé.
Pathologists have not always agreed on these distinctions, but we
have adhered to the view of Fisher and Adams that lacunes are
always due to occlusion of small arteries, 50 to 200 mm in diam-
eter, and the cribriform state to mere thickening of vessels and
fraying of the surrounding tissue—i.e., dilated perivascular spaces
that do not correlate with neurologic disease.

In almost all clinical and pathologic material, there has always
been a strong relationship between the lacunar state and a combi-
nation of hypertension and atherosclerosis and, to a lesser degree,
with diabetes. Sacco and colleagues (1991), in a population-based
study in Rochester, Minnesota, found hypertension in 81 percent
of patients with lacunar infarctions. In our view, the basis of the
lacunar state is unusually severe atherosclerosis that has extended
to the finest branches of large arteries.

When Fisher examined a series of such lesions in serial sec-
tions, from a basal parent artery up to and through the lacuna, he
found atheroma and thrombosis at the mouth of the branch vessels
and less often embolic occlusion of small vessels to be the basic
abnormality in some (usually the larger) lacunae, and a lipohyalin
degeneration and occlusion in the initial course of small vessels in
the smaller ones. In some, lipohyalinotic changes had resulted in
false aneurysm formation, resembling the Charcot-Bouchard an-
eurysms that underlie brain hemorrhage (see further on). In a series
of 1042 consecutive adults whose brains were examined postmor-
tem in past decades, Fisher observed one or more lacunae in 11
percent. He found 4 to 6 and sometimes up to 10 to 15 lacunae in
eye given brain specimen. In recent years, better treatment of hy-
pertension appears to us to have reduced this number, at least as
judged by MRI. Lacunae are situated, in descending order of fre-
cency, in the putamen and caudate nuclei, thalamus, basis pontis,
internal capsule, and deep hemispherical white matter. The cavities
range from 3 to 15 mm in diameter, and whether they cause symp-
toms depends entirely on their location.

Fisher has delineated the more frequent symptomatic forms:

1. Pure motor hemiplegia
2. Pure sensory stroke
3. Clumsy hand—dysarthria
4. Ipsilateral hemiparesis—ataxia

If the lacuna lies in the territory of a lenticulostriate artery,
i.e., in the internal capsule or adjacent corona radiata, it causes a
pure motor hemiplegia involving the face, arm, hand, leg, and foot.
A lacuna situated in the ventral pons may cause an identical syn-
drome. Symptoms may be abrupt in onset or evolve over several
hours, but in some instances (10 of 34 cases, according to Weis-
berg) the neurologic deficit evolves stepwise and relatively slowly,
over as long a period as 2 to 3 days, thereby simulating a small
hemorrhage. CT scanning shows the lesions in about two-thirds of
cases if several days have passed, and MRI in almost all cases
within hours of the stroke Sometimes the motor disorder takes the
form of a more limited hemiplegia of the face and arm or arm and
leg, or a dysarthria with or without hemiplegia. Recovery, which
may begin within hours, days, or weeks, is sometimes nearly com-
plete, even in the face of a severe initial stroke. However, many
patients are left with some degree of clumsiness or slowness of
movement of the affected side.

Similarly, a lacuna of the lateral thalamus or (less often of the
parietal white matter) presents as a pure hemisensory defect in-
volving the limbs, face, and trunk extending to the midline, a pure
sensory stroke. The incidence, course, and outcome are much the
same as in a pure hemiplegia.

**Figure 34-14.** Transverse section through the lower pons.
As mentioned, in the ventral pons, the lacunar syndrome may be one of pure motor hemiplegia, mimicking that of internal capsular infarction except for relative sparing of the face and the presence of an ipsilateral paresis of conjugate gaze in some cases; or there is a combination of dysarthria and clumsiness of one hand; in the latter case the lacune is located in the paramedian midpons on the side opposite the clumsy limb. Occasionally a lacunar infarction of the pons, midbrain, internal capsule, or parietal white matter gives rise to a hemiparesis with ataxia on the same side as the weakness (Fisher, Sage and Lepore). Some of the brainstem syndromes may blend with basilar branch syndromes. There are many other, less frequent lacunar syndromes, too numerous to tabulate here.

Multiple lacunar infarcts, involving the corticospinal and corticobulbar tracts, are by far the most common cause of pseudobulbar palsy. Undoubtedly, an accumulation of lacunes deep in both hemispheres can give rise to gait disorders and also to mental dulling sometimes referred to as multi-infarct dementia (see further on and pages 373, 691, and 707). The main differential diagnostic considerations are then normal-pressure hydrocephalus (Chap. 31) and degenerative brain conditions that affect the frontal lobes and basal ganglia (Chap 39).

In all these cases of lacunar infarction, the diagnosis depends essentially on the occurrence of the aforementioned unique stroke syndromes of limited proportions: to recapitulate, pure motor hemiplegia, pure sensory stroke, clumsy-hand with dysarthria, and ataxic hemiparesis are the main ones. As mentioned above, MRI is more reliable than CT scanning in demonstrating the lacunes. Initially, lacunes are seen on the MRI as deep oval or linear areas of T2, FLAIR, and especially diffusion weighted signal abnormality; later they become cavitated. The EEG may be helpful in a negative sense; in the case of lacunes in the pons or the internal capsule, there is a notable discrepancy between the unilateral paralysis or sensory loss and the negligible electrical changes over the affected hemisphere.

### THE MAJOR TYPES OF CEREBROVASCULAR DISEASE

In classifying the cerebrovascular diseases, it is most practical, from the clinical viewpoint, to preserve the classic division into thrombosis, embolism, and hemorrhage. The causes of each of the...
CHAPTER 34 CEREBROVASCULAR DISEASES

Figure 34-16. Transverse section through the upper pons.

Signs and symptoms

1. Medial superior pontine syndrome (paramedian branches of upper basilar artery)
   a. On side of lesion
      (1) Cerebellar ataxia
      (2) Internuclear ophthalmoplegia
      (3) Rhythmic myoclonus of palate, pharynx, vocal cords, respiratory apparatus, face, oculomotor apparatus, etc.
   b. On side opposite lesion
      (1) Paralysis of face, arm, and leg
      (2) Rarely touch, vibration, and position senses are affected

2. Lateral superior pontine syndrome (syndrome of superior cerebellar artery)
   a. On side of lesion
      (1) Ataxia of limbs and gait, falling to side of lesion
      (2) Dizziness, nausea, vomiting
      (3) Horizontal nystagmus
      (4) Paresis of conjugate gaze (ipsilateral)
      (5) Loss of optokinetic nystagmus
      (6) Skew deviation
      (7) Miosis, ptosis, decreased sweating over face (Horner syndrome)
   b. On side opposite lesion
      (1) Impaired pain and thermal sense on face, limbs, and trunk
      (2) Impaired touch, vibration, and position sense, more in leg than in arm (there is a tendency to incongruity of pain and touch deficits)

Structures involved

- Superior and/or middle cerebellar peduncle
- Medial longitudinal fasciculus
- Central tegmental bundle
- Corticobulbar and corticospinal tract
- Medial lemniscus
- Superior and/or middle cerebellar peduncles, superior surface of cerebellum, dentate nucleus
- Vestibular nuclei
- Territory of descending branch to middle cerebellar peduncle
- Vestibular nuclei
- Uncertain
- Superior cerebellar artery
- Descending sympathetic fibers
- Spinothalamic tract
- Medial lemniscus (lateral portion)

The frequency of the different types of cerebrovascular disease has been difficult to ascertain. Obviously clinical diagnosis is not always correct, and clinical services are heavily weighted with acute strokes and nonfatal cases of uncertain type. An autopsy series inevitably includes many old vascular lesions, particularly infarcts, whose exact nature cannot always be determined, and there...
is a bias also toward large fatal lesions (usually hemorrhages). Table 34-4 summarizes the findings of the Harvard Cooperative Stroke Registry, tabulated in 1978 and comprising 756 successive patients, each of whom was examined by a physician knowledgeable about strokes and subjected when necessary to appropriate ancillary examinations (four-vessel arteriography, CT scan, lumbar puncture, but before the days of MRI). For comparison, we have included an autopsy series of 748 cases, examined during the year 1949 by Fisher and Adams; of these, 179 (nearly 25 percent) had some form of cerebrovascular disease. Interestingly, in both series the ratio of infarcts to hemorrhages was 4:1 and embolism accounted for approximately one-third of all strokes. The above studies correspond reasonably well with more recent data collated in the Stroke Data Bank of the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) (Sacco et al., 1989) and other modern series which have had the advantage of MRI.

**Atherothrombotic Infarction**

Most cerebrovascular disease can be attributed to atherosclerosis and chronic hypertension; until ways are found to prevent or control them, vascular disease of the brain will continue to be a major cause of morbidity. Hypertension and atherosclerosis interact in a variety of ways. Atherosclerosis, by reducing the resilience of large arteries, induces systolic hypertension. In turn, sustained hypertension worsens atherosclerosis, seemingly “driving” it into the walls of small branch arteries (0.5 mm or less). All the coats of the vessel become impregnated with a hyaline-lipid material, a process that Fisher has called *lipohyalinosis*. The segment so affected may also weaken and allow the formation of a small dissecting aneurysm (Charcot-Bouchard aneurysm), which most neuropathologists hold responsible for the hypertensive brain hemorrhage.

The atheromatous process in brain arteries is identical to that in the aorta, coronary, and other large arteries. In general the process in the cerebral arteries runs parallel to but is somewhat less severe than that in the aorta, coronary, and lower limb vessels. There are many exceptions to this rule, however, and not infrequently a brain artery becomes occluded when there is no clinical evidence of coronary or peripheral vascular disease. Although atheromatosis is known to have its onset in childhood and adolescence, only in the middle and late years of life is it likely to have clinical effects. Hypertension, hyperlipidemia, and diabetes greatly aggravate the process. As with coronary and peripheral atherosclerosis, individuals with low blood levels of high-density-lipoprotein (HDL) cholesterol and high levels of low-density-lipoprotein (LDL) cholesterol are particularly disposed to cerebral atherosclerosis (Nubilia et al.). Long-duration cigarette smoking, an important factor in the genesis of atherosclerosis, decreases both HDL cholesterol and CBF (Ingall et al.). Added to these well-established risk factors is a theorized role of an excess of homocysteine and an even more speculative role for chronic inflammation or intra-cellular infection of uncertain origin within plaques (*Chlamydia pneumoniae* has been implicated in some studies). Clinical experience indicates that there are families with a predilection for the development of cerebral atherosclerosis, independent of these well-defined risk factors. Obesity is also a risk factor, in part because of its correlation with diabetes.

There is a tendency for atheromatous plaques to form at branchings and curves of the cerebral arteries. The most frequent sites are in the *internal carotid artery*, at its origin from the common carotid; in the *cervical part of the vertebral arteries* and at their junction to form the basilar artery; in the *stem or at the main bifurcation of the middle cerebral arteries*; in the *posterior cerebral arteries* as they wind around the midbrain; and in the *anterior cerebral arteries* as they pass anteriorly and curve over the corpus callosum. It is rare for the cerebral arteries to develop plaques beyond their first major branching. Also, it is unusual for the cerebellar and ophthalmic arteries to show atheromatous involvement except in conjunction with hypertension. The common carotid and vertebral arteries at their origins from the aorta are frequent sites of atheromatous deposits, but because of abundant collateral arterial pathways, occlusions at these sites are not commonly associated with cerebral ischemia.

The atheromatous lesions develop and grow silently for 20, 30, or more years; only in the event of a thrombotic complication do they become symptomatic. Although atheromatous plaques may narrow the lumen of an artery, causing stenosis, complete occlusion is nearly always the consequence of superimposed thrombosis (“atherothrombosis”). In general, the more severe the atheromatous, the more likely the thrombotic complication, but the two processes do not always run in parallel. One patient with only scattered atheromatous plaques may thrombose a vessel, whereas another with marked atherosclerosis may have only a few thrombosed vessels or none at all. Atheromatous lesions may regress to some extent under the influence of diet and certain drugs. Hennerici and colleagues followed a series of patients with carotid stenoses for a period of 18 months and observed spontaneous regression in nearly 20 percent of the lesions. In the large majority of cases, however, atherosclerosis is a progressive disease.

Degeneration of the wall of a sclerotic vessel or hemorrhage into the wall (from rupture of the vasa vasorum) may damage the endothelium. This is known to occur particularly in the walls of the internal carotid arteries (and the coronary arteries, where it is a main cause of vessel occlusion). The lesion in the atheromatous plaque apparently excites an inflammatory reaction. Platelets and fibrin then adhere to the damaged part of the wall and form delicate, friable clots, or a subintimal atheromatous deposit may slough, spewing crystalline cholesterol emboli into the lumen with result-

a Compiled by J. Mohr, L. Caplan, D. Pessin, P. Kistler, and G. Duncan at Massachusetts General Hospital and Beth Israel Hospital, Boston.

b Compiled by C. M. Fisher and R. D. Adams in an examination of 748 brains during the year 1949 at Mallory Institute of Pathology, Boston City Hospital.

c Hypertensive encephalopathy, cerebral vein thrombosis, meningeovascular syphilis, and polyarteritis nodosa.
ing occlusion of small distal vessels. In contrast to an embolus, a thrombus generally does not occlude the lumen completely from the first moment of its formation; total blockage may occur only after several hours. Once the lumen of the artery has been completely occluded, the thrombus may propagate distally and proximally to the next branching points and block an anastomotic channel.

These several dynamic events in the atherosclerotic-thrombotic process probably account for the prodromal ischemic attacks described below—intermittent blockage of the circulation and variable impairment of function in the vascular territory, before proceeding to permanent ischemia. Not infrequently, several arteries are affected by stenosis and thrombosis over a period of months or years. Then it becomes difficult to decipher the interplay of factors that have led to either transitory or persistent symptoms. Some of the possibilities have been outlined by Adams and colleagues (1961). The evolution of the thrombotic process may be sufficiently prolonged to explain the clinical state known as stroke in evolution; when the hemodynamic disturbance stabilizes, the stage of completed stroke is reached. These different stages acquire significance in relation to therapy and prognosis.

Pathophysiology of Thrombosis The process of thrombus formation involves an interplay between three components: the endothelium, circulating platelets, and a series of biochemical events that constitute a “coagulative cascade.”

When atherosclerosis is the primary condition, thrombus formation usually begins with a localized injury to the endothelium. As indicated earlier, the endothelium overlying a plaque suffers damage from hemorrhage or necrosis of the vessel wall secondary to an alteration of the vasa vasorum. Thrombus forms from fibrin and platelets that adhere to the endothelial surface and lead to partial or complete occlusion of the lumen. In the process, aggregates of platelets are attracted to the site, partly through the action of prostacyclin (derived from arachidonic acid). Also, a substance called vasomodulin on the surface of the endothelium—which, with protein C, normally inhibits the formation of fibrin through its interaction with thrombin—is reduced at the injured site and induces clotting. Homocystine has a similar effect and is believed thereby to promote thrombosis.

Circulating platelets increase in number locally, enlarge, and become more adherent to one another and to the injured vessel. As they aggregate, they discharge their granules. The latter process is stimulated by thromboxane A2, which is synthesized in the injured vessel wall. This substance also releases coagulation proteins (including thrombin and Willebrand factor and other elements of the coagulative cascade).

The third component—i.e., of the coagulative cascade—involves the complex interplay of the well known series of factors that results in the formation of thrombin and the conversion of fibrinogen to fibrin. Involved in this process are changes in a number of natural anticoagulative factors such as heparin cofactor 2, antithrombin III, protein C, and protein S. Some of these are extrinsic to the blood vessels and hence may result in thrombosis in one or in multiple sites even without prior vascular injury. Protein C is a vitamin K–dependent protease which, in combination with its cofactors protein S and antithrombin III, inhibits coagulation. A deficiency of any of these factors may predispose to in situ thrombosis within either the arterial or venous systems. For example, protein C deficiency (heterozygous in one of every 16,000 individuals) is a cause of thrombosis of both veins and arteries; a resistance to activated protein C has also been described (causing venous thrombosis almost exclusively). Antiphospholipid antibody is another cause of vascular occlusion that is not incited by damage to the vessel wall (see page 735). The metabolic disturbances in Fabry disease also favor clotting. Persons with certain inflammatory bowel diseases (ulcerative colitis, Crohn disease) are prone to develop thrombotic strokes. Whether inflammation elsewhere in the body also predisposes to cerebral vascular occlusions, as has been suggested, is an open question. Curiously, the hypercoagulable state induced by certain adenocarcinomas, does not produce in situ arterial occlusion (although it may precipitate cerebral venous thrombosis). Nevertheless, it does cause platelet-fibrin aggregation on cardiac valves with subsequent cerebral embolism (“marantic endocarditis,” as discussed further on).

These factors should be sought when thrombotic disease in cerebral arteries or veins occurs in children or young adults with unexplained strokes, in families with strokes, in pregnant or par- tulent women, and in women who are migraineurs or taking birth control pills (see further on). According to Markus and Hambley, whose review of this subject is recommended, screening for lupus anticoagulant, antiphospholipid antibodies, deficiency of proteins C and S, and antithrombin III is probably justified only in these special circumstances. These causes of vascular thrombosis are taken up in later sections.

Clinical Picture of Atherothrombotic Stroke In general, the evolution of clinical phenomena in relation to cerebral thrombosis is more variable than that of embolism and hemorrhage. In more than half of our patients, the main part of the stroke (paralysis or other deficit) is preceded by minor signs or one or more transient attacks of focal neurologic dysfunction, or TIA’s (Table 34-5). In a sense, these herald the oncoming vascular catastrophe. A history of such prodromal episodes is of paramount importance in establishing the diagnosis of atherothrombotic stroke. Only rarely and for unclear reasons are embolism and cerebral hemorrhage preceded by a transient neurologic disorder.

In carotid and middle cerebral artery disease, the transient attacks consist of monocular blindness or of hemiplegia, hemianesthesia, or disturbances of speech and language. In the vertebrobasilar system, the prodromal spells most often take the form of

episodes of vertigo, diplopia, numbness, impaired vision in one or both visual fields, and dysarthria. These TIA syndromes are described more fully further on. Such attacks last from a few minutes to several hours; in most instances the duration is less than 10 min. Those of several hours' duration have a different connotation, since they are usually due to demonstrable embolism. The final stroke may be preceded by one or two attacks or a hundred or more brief TIs, and the stroke may follow the onset of the attacks by hours, days, or less frequently by weeks or months. When there are no prodromal ischemic attacks, one must use other criteria to establish the diagnosis of atherosclerotic thrombosis.

The thrombotic stroke, whether or not it is preceded by warning attacks, finally develops in one of several ways. Most often there is a single episode but the whole illness evolves over a few hours or less. More characteristic is a “stuttering” or intermittent progression of neurologic deficits extending over several hours or a day or longer. This is a starkly different profile from the abrupt onset of a complete stroke syndrome that characterizes the embolic mechanism discussed further on. Again, in thrombosis a partial stroke may occur and even recede temporarily for several hours, after which there is rapid progression to the completed stroke—or several fleeting episodes may be followed by a longer one and, hours or a day or two later, by a major stroke. Several parts of the body may be affected at once or only one part, such as a limb or one side of the face, the other parts becoming involved serially in step-like fashion until the stroke is fully developed. Sometimes the deficit is episodic; spells of weakness or involuntary movement of a hand or arm or dimness of vision, lasting 5 to 10 min, occur spontaneously or are brought on by standing or walking. Each of the transient attacks and the abrupt episodes of progression reproduces the profile of the stroke in miniature. The principle of intermittency seems to characterize the thrombotic process from beginning to end.

As frequent as the modes of onset outlined above, and most characteristic of atherothrombotic events, is the occurrence of the stroke during sleep; the patient awakens paralyzed, either during the night or in the morning. Unaware of any difficulty, he may arise and fall helplessly to the floor with the first step. This is the story in fully 60 percent of our patients with thrombotic strokes and in a smaller number with embolic ones as well.

Most deceptive of all are the relatively few patients in whom the neurologic disorder has evolved over several days or even longer, in a slow, gradual fashion (“slow stroke”). One’s first impulse is to make a diagnosis of brain tumor, abscess, or subdural hematoma. This error can usually be avoided by a careful analysis of the course of the illness, which will disclose an uneven, saltatory progression; if the clinical data are incomplete, observation for a few days makes the stroke profile more apparent. Actually there are a few cases—and these are usually instances of pure motor hemiplegia—in which the evolution of a thrombotic stroke is eveny progressive over a period of days.

In addition to these several modes of evolution of atherothrombotic stroke, thrombotic stenosis or occlusion of certain large vessels may lead instead to the generation of embolic fragments (artery-to-artery embolus), thereby precipitating a new stroke in a region distal to the occlusion. This is most likely to occur during the period of clinical fluctuation and active thrombus formation. The most common occurrence of artery-to-artery embolism is with carotid artery thrombosis, the embolus passing to branches of the ipsilateral middle or anterior cerebral artery. With atherothrombotic blockage of the vertebral or lower basilar artery, the embolus originates in the occluded vessel but then proceeds to lodge in the posterior cerebral artery or the top of the basilar artery. In most of the cases of this nature that we have observed, there are additional telltale signs of slight pontine strokes (dysarthria, diplopia, see page 702.), presumably from the transient occlusion of the mouths of several small penetrating arteries as the embolus moves upward (“stop-and-go” or “traveling” embolus syndrome).

Arterial thrombosis is not usually accompanied by headache, but lateralized cranial pain occurs in some cases. Usually the pain is located on one side of the head in carotid occlusion, at the back of the head, or simultaneously in forehead and occiput in basilar occlusion, and behind the ipsilateral ear or above the eyebrow in vertebral occlusion. The headache is less severe and more regional than that of intracerebral or subarachnoid hemorrhage, and there is no stiffness of the neck. The mechanism is unclear; presumably it is related to the disease process or distention of the vessel wall, since it may antedate the other manifestations of the stroke by days or even weeks.

As mentioned in the introductory section, hypertension is more often present than not in patients with atherothrombotic infarction. Diabetes mellitus is common also, or the patient is a smoker or hyperlipidemic. Often there is evidence of vascular disease in other parts of the body: a history of coronary occlusion or angina pectoris, an electrocardiographic (ECG) abnormality reflecting a previous myocardial infarction or left ventricular hypertrophy, intermittent claudication, or an absence of one or several pulses in the lower limbs. The retinal arteries may show uniform or focal narrowing, increase and irregularity of the light reflex, and arteriovenous “nicking,” but these findings correlate with hypertension rather than atherosclerosis. The patient is more often elderly but may be in the fourth decade of life or even younger.

**Laboratory Findings**

These have been discussed at various points in the preceding pages and need only be recapitulated brieﬂy. In the laboratory investigation of atherothrombotic infarction, one may employ noninvasive techniques. Ultrasonography will reveal with fair accuracy the cervical and intracranial segments of the internal carotid and vertebralbasilar arteries. MRI is more sensitive to ischemic brain damage than is the CT scan. While the latter reveals hemorrhage immediately after it occurs, softened tissue cannot be seen until several days have elapsed. On the other hand, MRI reveals ischemic damage within a few hours, in both white and gray matter, and diffusion-weighted MRI techniques do so even earlier. The various MRI sequences are able to distinguish with reasonable clarity the age of cerebral infarction; the features that signify acute, subacute, and older strokes are summarized in Table 34-6 and discussed in Chap. 2. By MRA, one can see all the major cervical and intracranial arteries and may detect the irregular lumen or occlusion of atherosclerosis and even embolic occlusions in more distal vessels (Fig. 34-17). This method has to a large extent replaced conventional angiography, which is reserved for cases in which the diagnosis is in doubt (e.g., suspected angiitis) or when surgical intervention or long-term anticoagulant therapy is contemplated.

Lumbar puncture is now performed infrequently in patients with stroke. Cerebral thrombosis does not cause blood to enter the CSF. The CSF protein is sometimes slightly elevated (usually 50 to 80 mg/dL); rarely is it in excess of 100 mg/dL. A small number of polymorphonuclear leukocytes (3 to 8/mm³) is not exceptional in the first few days; very rarely, and for unexplained reasons, a brisk, transient pleocytosis (400 to 1000 polymorphonuclear leu-

Figure 34-17. Left carotid stenosis with border zone infarction demonstrated by MRI. Conventional angiography (right) show severe stenosis of the left internal carotid artery. The patient was a 72-year-old woman with acute onset of right hemiplegia.

Course and Prognosis When the patient is seen early in the course of cerebral thrombosis, it is difficult to give an accurate prognosis. One must ask where the patient stands in the stroke process at the time of the examination. Is worsening to be anticipated or not? No rules have yet been formulated that allow one to predict the early course with confidence. A mild paralysis today may become a disastrous hemiplegia tomorrow, or the patient’s condition may worsen only temporarily for a day or two. Anticoagulation and thrombolytic therapy may alter the course, as discussed further on. In basilar artery occlusion, dizziness and dysphagia may progress in a few days to total paralysis and deep coma. The course of cerebral thrombosis is so often progressive that a cautious attitude on the part of the physician in what first appears to be a mild stroke is justified.

As indicated above, progression of the stroke is due most often to increasing stenosis and occlusion of the involved artery by mural thrombus. In some instances, extension of the thrombus along the vessel may block side branches and hinder anastomotic flow. In the basilar artery, thrombus may gradually build up along its entire length.
length. In the carotid system, thrombus at times propagates distally from the site of origin in the neck to the supraclinoid portion and possibly into the anterior cerebral artery, preventing collateral flow from the opposite side. In middle cerebral occlusion, retrograde thrombosis may extend to the mouth of the anterior cerebral, perhaps secondarily leading to infarction of the territory of that vessel. And finally, abrupt progression of a stroke may be the result of artery-to-artery embolism, as described above.

Several other circumstances influence the immediate prognosis in cerebral thrombosis. In the case of very large infarcts, swelling of the infarcted tissue may occur, followed by displacement of central structures, transtentorial herniation, and death of the patient after several days (Fig. 34-18). This can be anticipated by the sheer volume of the infarct and is usually evident on the CT or MRI scan within a day of the stroke. Smaller infarcts of the inferior surface of the cerebellum may also cause a fatal herniation into the foramen magnum. Milder degrees of swelling and increased intracranial pressure may progress slightly for 2 to 3 days but do not prove fatal. In extensive brainstem infarction associated with deep coma due to basilar artery occlusion, the early mortality rate approaches 40 percent. In any type of stroke, if coma or stupor is present from the beginning, survival is largely determined by success in keeping the airway clear, controlling brain swelling, preventing aspiration pneumonia, and maintaining fluid and electrolyte balance, as described further on under “Treatment of Cerebral Edema and Raised Intracranial Pressure.” With smaller thrombotic infarcts, the mortality is 3 to 6 percent, much of it from myocardial infarction and aspiration pneumonia.

As for the eventual or long-term prognosis of the neurologic deficit, there are many possibilities. Improvement is the rule if the patient survives. The patient with a lacunar infarct and pure motor hemiparesis usually fares well. With other small infarcts, recovery may start within a day or two, and restoration may be complete or nearly complete within a week. In cases of severe deficit, there may be no significant recovery; after months of assiduous efforts at rehabilitation, the patient may remain bereft of speech and understanding, with the upper extremity still useless and the lower extremity serving only as an uncertain prop during attempts to walk. Between these two extremes there is every gradation of recovery. In general, and not surprisingly, the longer the delay in onset of recovery, the poorer the prognosis. Measurement of central motor conduction by magnetic stimulation has been predictive of recovery and survival but is not widely used for clinical work. If clinical recovery does not begin in 1 or 2 weeks, the outlook is gloomy for both motor and language functions. Constructional apraxia, uninhibited anger (with left and rarely with right temporal lesions), nonsensical logorrhea and placidity, unawareness of the paralysis and neglect (with nondominant parietal lesions), and confusion and delirium (with nondominant temporal lesions) all tend to diminish and may disappear within a few weeks. A hemianopia that has not cleared in a few weeks will usually be permanent, although reading and color discrimination may continue to improve. In lateral medullary infarction, difficulty in swallowing may be protracted, lasting 4 to 8 weeks or longer; yet relatively normal function is finally restored in nearly every instance. Aphasia, dysarthria, cerebellar ataxia, and walking may improve for a year or longer, but for all practical purposes it may be said that whatever motor and language deficits remain after 5 to 6 months will be permanent.

Characteristically, the paralyzed muscles are flaccid in the first days or weeks following a stroke; the tendon reflexes are usually unchanged but may be slightly increased or decreased. Gradually spasticity develops, and the tendon reflexes become brisker. The arm tends to assume a flexed adducted posture and the leg an extended one. Function is rarely if ever restored after the slow evolution of spasticity (however, the use of botulinum toxin may help considerably in relieving the spasticity). Conversely, the early de-

Figure 34-18. Massive ischemic infarct of left cerebral hemisphere mainly in the distribution of the superior division of the middle cerebral artery. CT scans taken 24 h (left) and 72 h (right) following the onset of neurologic symptoms. The second scan demonstrates marked swelling of the infarcted tissue and displacement of central structures.
development of spasticity in the arm or the early appearance of a grasp reflex may presage a favorable outcome. In some patients with extensive temporoparietal lesions, the hemiplegia remains flaccid; the arm dangles and the slack leg must be braced to stand. The physiologic explanation of this remains obscure. If the internal capsule is not interrupted completely in a stroke that involves the lenticular nucleus or thalamus, the paralysis may give way to hemichoreoathetosis, hemitremor, or hemiataxia, depending upon the particular anatomy of the lesion. Bowel and bladder control usually returns; sphincteric disorders persist in only a few cases. Often the hemiplegic limbs are at first tender and ache on manipulation. Nevertheless, physiotherapy should be initiated early in order to prevent pseudocontracture of muscles and periartthritis at the shoulder, elbow, wrist, knuckles, knee, and ankle. These are frequent complications and often the source of pain and added disability, particularly of the shoulder. Occasionally, atrophy of bone and pain in the hand may accompany the shoulder pain (shoulder-hand syndrome). An annoying feeling of dizziness and unsteadiness often persists after damage to the vestibular system in brainstem infarcts.

Convulsive (epileptic) seizures are relatively uncommon sequelae of thrombotic strokes in comparison to embolic cortical infarcts, which are followed by seizures in up to 10 percent of patients. Most often in our experience, the EEG in these cases had never normalized and showed sharp activity over the region of the infarct even many months after the stroke (see further on for advice on the treatment of seizures after stroke).

Many patients complain of fatigability and are depressed, possibly more so after strokes that involve the left frontal lobe (Starkstein et al). The explanation of these symptoms is uncertain; some are certainly expressions of a reactive depression. Only a few patients develop serious behavior problems or are psychotic after a stroke, but paranoid trends, confusion, ill temper, stubbornness, and peevishness may appear, or an apathetic state ensues. Large lesions affect concentration as well as synthetic and executive mental functions in general proportion to their size; these mental changes are independent of any disturbances in language function.

Finally, in regard to prognosis, it must be mentioned that having had one thrombotic stroke, the patient is at increased risk in the ensuing months and years of having a stroke at the same or another site, especially if there is hypertension or diabetes mellitus. When multiple infarcts occur over a period of months or years, special types of dementia may develop, in addition to focal cerebral deficits. In some of these cases, the major lesions involve the white matter, with relative sparing of the cortex and basal ganglia; the lesions may be lacunar or larger in size. This disorder, often referred to as Binswanger subcortical leukoencephalopathy, probably represents the accumulation of multiple white matter infarcts and lacunes (pages 707 and 909) (see Mohr and Mast and Babikian and Ropper). The parts of the white matter that are destroyed tend to lie in the border zones between the penetrating cortical and basal ganglionic arteries. The large patches of subcortical myelin loss and gliosis, in combination with small cortical and subcortical infarcts, produce a special radiologic image. This still incompletely understood process and the histologically similar but biologically unique inherited condition of white matter termed CADASIL are discussed further on.

During the period 1970–1974 in Rochester, Minnesota, 94 percent of patients with ischemic strokes survived for 5 days and 84 percent for 1 month (Garraway et al). The survival rate was 54 percent at 3 years and 40 percent at 7 years. In each of these groups, survival was significantly greater than it had been during the period 1965–1969. Among long-term survivors, heart disease is a more frequent cause of death than additional strokes. These figures, which were gathered retrospectively, are comparable to more recent ones reported by Bamford and colleagues. The mortality rate following cerebral infarcts in general (no separation being made between thrombotic and embolic types) at the end of 1 month was 19 percent and at the end of 1 year, 23 percent. Of the survivors, 65 percent were capable of an independent existence. Our colleague J. Hincheys has repeatedly pointed out that pneumonia as a result of faulty swallowing is a major determinant of survival; further discussion regarding aspiration problems following stroke are to be found on pages 477 and 699.

**Transient Ischemic Attacks**

As has already been emphasized, when brief transient ischemic attacks (TIAs) precede a stroke, they almost always stamp the underlying process as atherothrombotic. There is little doubt that they are due to transient focal ischemia, but their precise mechanism is not fully understood (see further on); they might be thought of as temporary strokes that fortunately reverse themselves. They belong, therefore, under the heading of atherosclerotic thrombotic disease but are discussed separately here because of their clinical importance.

Current opinion holds that TIAs are brief, reversible episodes of focal, nonconvulsive ischemic neurologic disturbance. The consensus had been that their duration should be less than 24 h, an idea introduced 30 years ago by a committee assigned to study the problem. It is more useful, however, to separate attacks that last only a few minutes (up to 1 h) and leave no permanent signs, from those of longer duration which are more likely to be due to embolism. In any clinical analysis of TIAs, it is also important to separate a single transient episode from repeated ones that are all of uniform type. The latter are more often a warning sign of impending vascular occlusion, particularly of the internal carotid artery, while the former, especially when prolonged are often due to an embolus that leaves no lasting effect. It should also be pointed out that blood diseases that cause excessive viscosity or sludging of blood (polycythemia vera, sickle-cell disease, thrombocytosis, leukemia, and hyperglobulinemic states) may also cause TIAs prior to a stroke.

In a prospective study of 390 patients with focal TIAs caused by atherosclerotic vascular disease, the 5-year cumulative rate of fatal or nonfatal cerebral infarction was 23 percent (Heyman et al). Interestingly, the rate of myocardial infarction in this group of patients, particularly in those with carotid lesions, was almost as high (21 percent) and in other series, it has exceeded the risk of stroke. Thus the occurrence of carotid TIAs is a predictor not only of cerebral infarction but also of myocardial infarction. About two-thirds of all patients with TIAs are men with hypertension, reflecting the higher incidence of atherosclerosis in this group. Occasionally, in younger adults, TIAs may occur as relatively benign phenomena, without recognizable features of atherosclerosis or risk factors for it. Migraine is suspect in such patients (see page 151); other such instances are due to special hematologic disorders such as the antiphospholipid antibody discussed later in the chapter.

**Clinical Picture** Transient ischemic attacks can reflect the involvement of virtually any cerebral artery: common or internal carotid; middle, posterior, or anterior cerebral; ophthalmic; vertebral,
basilar, or cerebellar; or a penetrating branch to the basal ganglia or brainstem (lacunar TIAs). If the posterior cerebral arteries are considered with the vertebrobasilar system, transient ischemic episodes are slightly more common in this system than in the field of the carotid territory. TIAs may precede, accompany, or infrequently follow the development of a stroke, or they can occur by themselves without leading to a stroke—a fact that makes any form of therapy difficult to evaluate.

As just noted, TIAs that presage stroke may last a few seconds or up to an hour, longer ones almost certainly being due to embolic infarction. Most last 2 to 15 min. There may be only a few attacks or several hundred. Between attacks, the neurologic examination discloses no abnormalities. A stroke may occur after the first or second episode or only after numerous attacks have occurred over a period of weeks or months. Not infrequently the attacks gradually cease and no important paralysis occurs. So far it has not been possible to distinguish those individuals in whom a stroke will develop from those in whom it will not except in a general way. Many attacks which appear over a long period of time tend to be less likely to lead to thrombosis. Prolonged, fluctuating TIAs are the most ominous. About 20 percent of infarcts that follow TIAs occur within a month after the first attack, and about 50 percent within a year (see Whisnant et al, 1973).

Hemispheric Transient Ischemic Attacks (Carotid Artery Territory) The neurologic features of the transient episode indicate the territory or artery involved and are fragments of the stroke that may be approaching. In the carotid system, TIAs indicate involvement of one cerebral hemisphere or eye. The visual disturbance is ipsilateral; the sensorimotor disturbance is contralateral. Individual attacks tend to involve either the eye or the brain; only rarely are the two involved simultaneously. In the hemispheric attacks, ischemia occurs mainly in the distal territory of the middle cerebral artery or in an adjacent border zone, producing weakness or numbness of the opposite hand and arm. However, many different combinations may be seen: face and lips, lips and fingers, fingers alone, hand and foot. Rather than being paralyzed or weak, the arm may shake irregularly, simulating a seizure (“limb-shaking TIA”) or rarely display other transient movement disorders (Yanagihara et al). Less common manifestations include confusion, aphasia and difficulty in calculation (when the dominant hemisphere is involved), apraxia, amnesia (nondominant hemisphere), and other temporoparietal disturbances. Headache is not a feature of TIAs.

In ocular attacks, transient monocular blindness (also called amaurosis fugax) is the usual symptom. Most of these episodes evolve swiftly, over 5 to 30 s, and are described as a horizontal shade falling (or rising) smoothly over the visual field until the eye is completely but painlessly blind. The attack clears slowly and uniformly. Sometimes the attack takes the form of a wedge of visual loss, sudden generalized blurring, or, rarely, a gray or bright light. Transient attacks of monocular blindness are usually more stereotyped than hemispheric attacks. TIAs consisting of a homonymous hemianopia and paresthesias of the hand and arm should suggest a stenosis of the posterior cerebral artery.

The implications of amaurosis fugax have been evaluated by several investigators and found not to be quite as ominous as those of hemispheric TIAs, particularly in younger patients. Poole and Ross Russell observed a group of 110 patients for periods of 6 to 19 years following an episode of amaurosis fugax (exclusive of the type caused by cholesterol emboli). At the end of 6 years, the mortality rate (due mainly to heart disease) had risen to 21 percent and the incidence of stroke to 13 percent (compared to expected figures of 15 and 3 percent, respectively, in an age-matched population). Of the patients who were alive at the end of the observation period, 43 percent had had no further attacks of amaurosis fugax following the initial episode. Noteworthy also was the finding that among patients with normal carotid arteriograms, only 1 of 35 had a stroke during the follow-up period, whereas stroke had occurred in 8 of 21 patients in whom the internal carotid artery was occluded or stenotic. These figures are in keeping with those of Ackerman; in his series of 139 patients with amaurosis fugax and normal lumens of the common and internal carotid arteries, only 3 had a subsequent hemispheric stroke (personal communication). As pointed out by Benavente and colleagues, the risk of stroke over the 3 years following an attack is as low as 2 percent if there are no other issues such as diabetes, but it may be as high as 24 percent in older patients with risk factors for atherosclerosis. The age of the patient with amaurosis fugax is of particular significance. In the series of Poole and Ross Russell, the youngest patient to have a stroke after amaurosis fugax was 57 years old. Tippin and co-workers reviewed the records of 83 patients with onset of amaurosis fugax before the age of 45 years and found evidence of stroke in none; moreover, 42 of these patients were examined after a mean period of 5.8 years during which no stroke had occurred. It is evident that in this early-onset, good-prognosis group, a mechanism other than atherosclerosis was operative, such as migraine or an antiphospholipid antibody (discussed further on).

Brainstem Transient Ischemic Attacks (Vertebrobasilar Circulation) Recurrent TIAs referable to vertebrobasilar disease tend to be less stereotyped and more prolonged than those related to the carotid circulation. They are also more likely to culminate in a stroke. The clinical picture of TIAs in the vertebrobasilar territory is diverse, since this circulation sustains such a varied sensory-motor traffic. Vertigo, diplopia (vertical or horizontal), dysarthria, bifacial numbness, ataxia, and weakness or numbness of part or all of one or both sides of the body (i.e., a disturbance of the long motor or sensory tracts bilaterally) are the hallmarks of vertebrobasilar involvement. Transient vertigo, diplopia, or headache occurring as solitary symptoms should not be interpreted as a TIA. Also, in some patients, the complaint of dizziness will prove, however infrequently, to be part of a carotid TIA; hence this symptom, in our experience and that of Ueda et al, is not a totally reliable indicator of the vascular territory involved. Other manifestations of vertebrobasilar TIAs, in their approximate order of frequency, include staggering, veering to one side, a feeling of cross-eyedness, dark vision, blurred vision, tunnel vision, partial or complete blindness, pupillary change, ptosis, paralysis of gaze, dysarthria, and dysphagia. Less common symptoms include hemiplegia, noise or pounding in the ear or in the head, pain in the head or face or other peculiar head sensations, vomiting, hiccups, sense of tilting, lapse of memory, confused behavior, drowsiness, transient unconsciousness (rare), impaired hearing, deafness, hemiballismus, hallucinosis, and forced deviation of the eyes. So-called drop attacks (page 329), according to Ross Russell, have been recorded in 10 to 15 percent of patients with vertebrobasilar insufficiency, but we have never observed such attacks as a recurrent ischemic phenomenon or a manifestation of other forms of cerebrovascular disease.

Vertebrobasilar TIAs may be identical from one episode to another, or they may vary in detail while maintaining the same basic pattern, the latter occurrence being more typical. For exam-
ple, weakness or numbness may involve the fingers and face in some episodes and only the fingers in others; or dizziness and ataxia may occur in some attacks, while in others diplopia is added to the picture. In basilar artery disease, each side of the body may be affected alternately. All the involved parts may be affected simultaneously, or a march or spread from one region to another may occur over a period of 10 s to a minute or a few minutes—much slower than the spread of a seizure. The individual attack may cease abruptly or fade gradually.

**Lacunar Transient Ischemic Attacks** It has been recognized that strokes due to occlusion of small penetrating vessels of the brain have a proclivity to be intermittent (“stuttering”) at their onset and occasionally to allow virtually complete restitution of function between discrete episodes. Whether this constitutes a lacunar TIA has been debated, but it seems to us that the problem is our inability to distinguish a transitory occlusion of a small vessel from that of a larger vessel. Donnan and colleagues speak of a “capsular warning syndrome,” which we have seen a number of times, consisting of escalating episodes of weakness in the face, arm, and leg and culminating in a capsular lacunar lesion. These “lacunar TIAS” may stutter or remit, and there is no doubt that one or many of them may precede a lacunar stroke.

**Mechanism of Transient Ischemic Attacks** The question here, so far not satisfactorily answered, is whether low flow or embolic particles are responsible for TIAS. Whatever the exact cause of the attacks, they are in most cases intimately related to vascular stenosis and, usually, to ulceration due to atherosclerosis and to thrombus formation. Embolization of fibrin-platelet material from atherosclerotic sites may indeed be the cause of attacks in some cases, but it is difficult to understand, in attacks of identical pattern, how successive emboli from a distance would enter the same arterial branch each time. Moreover, one would expect the involved cerebral tissue to be at least partially damaged, leaving some residual signs. When a single transient episode has occurred, the factor of recurrence does not enter into the diagnosis, and cerebral embolism must then be strongly considered. In some cases of documented embolism, the neurologic state fluctuates from normal to abnormal repeatedly for as long as 36 h, giving the appearance of TIAs (“accelerated TIAS”); in others, a deficit of several hours’ duration occurs, fulfilling the traditional (now largely discarded) criterion of TIAs. As already noted, the same sequence of events can precede lacunar infarction and seem most likely to be due to locally reduced blood flow. Again, a single transitory episode, especially if it lasts longer than 1 h, and multiple episodes of different pattern, suggest embolism and must be distinguished from brief (2- to 10-min) recurrent attacks of the same pattern, which suggest atherosclerosis and thrombosis in a large cerebral or feeding vessel.

Ophthalmoscopic observations of the retinal vessels made during episodes of transient monocular blindness show either an arrest of blood flow in the retinal arteries and breaking up of the venous columns to form a “boxcar” pattern or scattered bits of white material temporarily blocking the retinal arteries. These observations indicate that in some cases of ischemic attacks involving the retinal vessels, a temporary, complete, or relatively complete cessation of blood flow occurs locally and that the cause is sometimes microembolism.

TIAs have in the past been attributed to cerebral vasospasm or to transient episodes of systemic arterial hypotension with resulting compromise of the intracranial circulation, but neither of these mechanisms is likely in the typical case. Although hypotension may cause focal EEG changes, it has not, in the authors’ experience, reproduced the attacks in either the carotid or basilar territory. In the majority of cases, the attacks bear no strict relation to position or activity, although they are likely to occur when the patient is up and around rather than lying down. Nevertheless, a small proportion of patients with carotid or basilar artery stenosis clearly relate the onset of their attacks to standing up after lying or sitting. Transient symptoms present on awakening from sleep usually indicate that a stroke is impending. Rarely, TIAs are experienced in relation to exercise, outbursts of anger or joy, and bouts of coughing.

On the other hand, exercise and postural TIAs are particularly suggestive of stenosis of aortic branches, as occurs in Takayasu disease (see further on) and dissection of the aortic arch and occasionally in a fixed carotid stenosis. TIAs induced by hyperventilation are said to be characteristic of moyamoya disease, a progressive stenosis of intracranial vessels discussed in a later section.

In states of anemia, polycythemia, thrombocytopenia, extreme hyperlipidemia, hyperviscosity from macroglobulinemia, sickle cell anemia, and hypoglycemia, there may be transient neurologic deficits related to rheologic changes in blood, as already mentioned. In some of these cases, stenosis in a large or small vessel appears to have accounted for a restricted neurologic deficit, but just as often the vasculature is normal. Patients with antiphospholipid antibodies may have TIAs, the mechanism of which is undefined.

In some instances the TIAs begin after the artery has already been occluded by thrombus. As shown by Barnett, emboli may arise from the distal end of the thrombus or enter the upper part of the occluded vessel through a collateral artery. However, almost one-fifth of “carotid TIAs” in the series of Pessin and colleagues and a somewhat larger proportion of cases reported by Ueda and coworkers had neither stenosis nor ulceration of the carotid arteries. In most of the cases with normal carotids, the ischemic attacks exceeded 1 h in duration, suggesting embolism from the heart or great vessels including the aortic arch; but there were also a small number of brief ischemic attacks that were unexplained even after arteriography.

In general, hemodynamic changes in the retinal or cerebral circulation make their appearance when the lumen of the internal carotid artery is reduced to 1.5 mm or less (normal diameter, 7.0 mm; range, 5 to 10 mm, smaller part of this range in women). This corresponds to a reduction in cross-sectional area of more than 95 percent. The exact degree of stenosis that may cause TIAs and the risk of stroke with mild and moderate degrees of stenosis is controversial and is addressed further on.

**Differential Diagnosis of Transient Ischemic Attacks** Transient focal neurologic symptoms are ubiquitous in neurologic practice. They may be due to seizures, migraine, or unusual conditions such as transient global amnesia (page 379), and they occur occasionally in patients with multiple sclerosis. Almost always the clinical setting in which they occur indicates the nature of the attack. Transient episodes, indistinguishable from TIAs, are also known to occur in patients with meningioma, glioblastoma, metastatic brain tumors situated in or near the cortex, and even with subdural hematoma. Although infrequent, these attacks are important mainly because the use of anticoagulants is relatively contraindicated in some of these circumstances. The episodes that we have seen with meningiomas and subdural hematomas have consisted mainly of transient aphasia or speech arrest lasting from 2
min to several hours, but sensory symptoms with or without spread over the body, arm weakness, and hemiparesis have also been reported. Some remarkable cases of meningioma have involved repeated transient attacks for decades. Seizures are always suspected in these cases but cannot be proved. It has been speculated that a local vascular disturbance of some kind is operative, but the mechanism is not understood.

**Treatment of Atherothrombotic Infarction and Transient Ischemic Attacks**

The main objective in these forms of cerebrovascular disease is the prevention of stroke. Ideally this should be accomplished by finding patients in the asymptomatic stage of atherosclerosis. However, the medical profession has no efficient means of screening large populations at risk of developing stroke and only limited methods for altering the progression of the atherosclerotic process, even if discovered in its early stages. The widespread use of cholesterol-lowering “statin” medications has been shown to reduce the incidence of stroke and will probably be more widely prescribed to normal older adults. For all practical purposes, treatment is directed to patients who have already begun to have symptoms, either TIs or ischemic lesions that are reversible to some extent.

The current treatment of atherothrombotic disease may be divided into four parts: (1) management in the acute phase, (2) measures to restore the circulation and arrest the pathologic process, (3) physical therapy and rehabilitation, and (4) measures to prevent further strokes and progression of vascular disease.

**Management in the Acute Phase** The relative advantages of placing the seriously ill acute stroke patient in a neurologic special care or “stroke” unit have been the subject of many articles. It is our impression that the outcome—in terms of morbidity and mortality in the seriously ill stroke patient—is improved, though admittedly this is difficult to document (for details, see Ropper and also Brott and Reed). Like the well-organized coronary care unit, stroke units have the capability of expediting the evaluation and early rehabilitation of these patients. As already emphasized, the prevention of aspiration and of pneumonia are paramount, and probably avoidable. Also deserving attention are the prevention of venous thrombosis in the legs, pulmonary embolism, and coronary syndromes. Patients with impaired consciousness require special care of skin, eyes, mouth, bladder, and bowel. These measures are best provided in a unit with trained clinical staff and the technology to monitor blood pressure, pulmonary function, blood gases, and, when appropriate, intracranial pressure (page 740).

**Measures to Restore the Circulation and Arrest the Pathologic Process** Once a thrombotic stroke has developed fully (i.e., the completed stroke), none of the therapeutic measures so far devised has proved to be consistently effective in restoring the damaged cerebral tissue to a functional state. The influence of anticoagulants and thrombolyis at an early stage of stroke are discussed below. One’s efforts must be directed to making a diagnosis of thrombosis at the earliest possible stage and circumventing the full catastrophe by all means available without risking the safety of the patient. Even when the symptoms and signs have become persistent, it is conceivable that some of the affected tissue, particularly at the edges of the infarct, has not been irreversibly damaged and will survive if perfusion can be re-established. On the assumption that cerebral perfusion might be diminished by assuming the upright position, it is probably advisable for patients with a major stroke to remain nearly horizontal in bed for the first day. When sitting and walking begin, special attention should be given to maintenance of normal blood pressure (patients should avoid standing quietly or sitting with the feet down for prolonged periods, etc.).

Several studies have confirmed the prevalence of new or exaggerated hypertension following an ischemic stroke and its tendency to decline within days even without medications. The treatment of previously unappreciated hypertension is preferably deferred until the neurologic deficit has stabilized. We agree with Britton and colleagues that it is prudent to avoid antihypertensive drugs in the first few days unless there is active myocardial ischemia or the blood pressure is high enough to pose a risk to other organs, particularly the kidneys, or there is a special risk of cerebral hemorrhage as a result of the use of thrombolytic drugs.

**Thrombolytic Agents** Tissue plasminogen activators (recombinant t-PA and streptokinase), when administered intravenously, convert plasminogen to plasmin, the latter being a proteolytic enzyme capable of hydrolyzing fibrin, fibrinogen, and other clotting proteins. These drugs are effective in the treatment of coronary artery occlusion (but are associated with a 1 percent risk of cerebral hemorrhage), and they also have now been shown to have a role in the treatment of stroke.

The multicenter study organized by the National Institute of Neurological and Communicative Disorders and Stroke (see the NINCDS and Stroke rt-PA Stroke Study Group in the References) has provided evidence of benefit from intravenous t-PA. Treatment within 3 h of the onset of symptoms led to a 30 percent increase in the number of patients who remained with little or no neurologic deficit when re-examined 3 months after the stroke and when assessed 1 year later in the study by Kwiatkowski et al. It is not easy to comprehend why the benefits apparently extended to all types of ischemic stroke, including those due to occlusion of small vessels (lacunes), and why improvement was not at all apparent in the days immediately following treatment, only much later. The t-PA was administered in a dose of 0.9 mg/kg, 10 percent of which was given as an initial bolus, followed by an infusion of the remainder over 1 h. A dose of 90 mg was not exceeded, this being lower than the dose used for myocardial infarction. The relative improvement in neurologic state came at the expense of a 6 percent risk of symptomatic cerebral hemorrhage, i.e., a far lower rate than in most previous studies (some of the hemorrhages were into the area of infarction without causing symptomatic worsening). Patients with massive infarcts (ones that encompassed more than two-thirds of the territory of the middle cerebral artery) or with high scores on a clinical stroke scale devised for the National Institutes of Health (NIH) study or with uncontrolled hypertension or who were more than 80 years of age or who had recently received anticoagulants (except aspirin) were excluded from this study. Further analysis of the NINCDS trial has revealed that patients who were treated earlier within the 3-h time frame had more benefit than those treated later; indeed, the administration of t-PA in the time period between 2.5 and 3 h after the stroke was of little value.

Comparable data from the randomized European Cooperative Acute Stroke Study (ECASS; see Hacke et al), which included 620 patients, identified two situations in which t-PA administered intravenously within 6 h, at a slightly higher dose than in the above trial (1.1 mg/kg, to a maximum of 100 mg), led to an improved neurologic outcome, but the overall results of this trial were con-
sidered to be unfavorable largely because of a high rate of cerebral hemorrhage. In a second trial (ECASS II) in 800 patients, using the same dose as in the NINCDS-sponsored trial but giving the thrombolytic drug up to 6 h after the stroke, no benefit could be confirmed and the rate of symptomatic hemorrhage was 8.8 percent (compared with 3.4 percent in untreated patients). Yet a subgroup of patients with carotid-middle cerebral artery strokes of moderate severity—specifically those with moderate-sized infarcts from occlusion of vessels distal to the carotid artery and adequate collateral circulation through surface vessels—did appear to benefit. In some patients with basilar artery occlusion with coma of only brief duration and those without extensive thrombosis, prompt t-PA treatment also resulted in an overall improvement in neurologic function, but there were numerous exceptions.

In all these trials, patients with large cerebral infarctions had poor outcomes and suffered a high incidence of cerebral hemorrhage. It has been concluded, therefore, that the presence of blood in the first CT scan and evidence of extensive infarction, occupying most of the MCA territory, precludes this mode of therapy. In two similar trials conducted by the European MAST-I groups (see the Multicentre Acute Stroke Trial in References), using streptokinase within 6 h of stroke, there was actually an adverse outcome—the treated group having an excess of early deaths; this trial had a 21 percent incidence of symptomatic cerebral hemorrhage and an 18 percent incidence of hemorrhagic infarctions.

At the present time the use of intravenous t-PA therapy can be advocated only in patients who arrive in the emergency department and can be fully evaluated within 3 h of the onset of a stroke, preferably even earlier (thus excluding those who awaken from a night’s sleep with the symptoms) and have no hemorrhage on the CT scan. Generally also excluded are those in whom the deficit is either very small (e.g., hand affected only, dysarthria alone, minor aphasia) or, more importantly, so large as to implicate the entire territory of the middle cerebral artery. Although seemingly a promising approach to acute stroke, the use of acute thrombolytic therapy depends on the very early identification of a restricted group of patients; therefore this therapy is applicable to only a limited proportion of stroke patients who present to the emergency department (approximately 5 percent) or those who have strokes while under observation in the hospital. It is noteworthy that attempts to reproduce the beneficial effects of t-PA in a community setting have been disappointing largely because of deviations from treatment guidelines and an excess number of hemorrhages (Katzan et al). Nonetheless, acute intravenous thrombolyis that is managed closely by experienced individuals using validated protocols is a compelling treatment at the moment for acute ischemic stroke. Public health education should increase the numbers of stroke patients who seek early attention and thus raise the proportion who are eligible for t-PA treatment.

Thrombolytics injected intra-arterially can in some instances dissolve occlusions of the middle cerebral and basilar arteries and, if administered within hours, reduce the neurologic deficit. However, the routine intra-arterial injection of thrombolytics into infarcted tissue has produced a high incidence of cerebral hemorrhage, approaching 20 percent in some studies and leaving the overall morbidity about the same in treated and untreated patients. There is also a high incidence of reocclusion of the treated vessel. The exception, in our limited experience, has been basilar artery thrombosis without cerebellar infarctions, where large neurologic deficits are at times reversed with fewer complications. Treatment even several hours after the first symptoms may stop progression, but the lack of a systematic study of this approach makes it difficult to endorse without reservation. Mechanical lysis of an intra-arterial clot may be as effective.

**Acute Surgical Revascularization** Rarely is the patient who has had a stroke brought to medical attention within a few minutes of onset, although this may happen when a patient is in the hospital for another reason. If it can be established that the common or internal carotid artery has just become thrombosed, intravenous or preferably intra-arterial t-PA or mechanical lysis of the clot may be effective. We have had some experience with immediate surgical removal of the clot or the performance of a bypass to restore function. Ojemann and colleagues operated on 55 such patients as an emergency procedure; 26 of these had stenotic vessels and 29 acutely thrombosed vessels. Of the latter, circulation was restored in 21, with an excellent or good clinical result in 16. In 26 patients with stenotic carotid arteries, an excellent or good result was obtained in 19. Usually several hours will have elapsed before the diagnosis is established. If the interval is longer than 12 h, opening the occluded vessel is usually of little value and may present additional dangers. Reoperation after carotid endarterectomy is a special circumstance in which rapid removal of a clot is performed more or less routinely.

**Treatment of Infarctive Cerebral Edema and Raised Intracranial Pressure** In the first few days following massive cerebral infarction, brain edema of the necrotic tissue may threaten life. Most often this occurs with a complete infarction in the territory of the middle cerebral artery; some degree of mass effect is evident on a CT scan in the first 24 h. Additional infarction in the territory of the anterior cerebral artery (total carotid occlusion) worsens the situation. Clinical deterioration occurs within several days of the stroke (usually worst on the third day, sometimes later) but may evolve as quickly as several hours after the onset (Fig. 34-18). The clinical signs of worsening—drowsiness, a fixed (but not necessarily enlarged) pupil, and a Babinski sign on the side of the infarction—are all due to secondary tissue shifts, as described in Chaps. 17 and 30. In such instances, controlled hyperventilation may be useful as a temporizing maneuver. Frank has shown that clinical deterioration is not always associated with an initial elevation of intracranial pressure. It may therefore be advisable, in selected cases, to measure the ICP directly before embarking on an aggressive medical regimen to lower the pressure.

*Intravenous mannitol* in doses of 1 g/kg, then 50 g every 2 or 3 h, may forestall further deterioration, but most of these patients, once comatose, are likely to die unless drastic measures are taken. Corticosteroids are probably of little value; several trials have failed to demonstrate their efficacy.

In the past several years there has been a renewed interest in *hemicraniectomy* as a means of reducing the mass effect and intracranial pressure in these extreme circumstances. Our success in salvaging several patients even after a period of coma—similar to reported series by Schwab, Carter, Delshaw, and Rengachary and coworkers—indicates that hemicraniectomy combined with an overlying duraplasty may be undertaken if the patient is progressing from a stuporous state to coma and imaging studies show increasing mass effect. Of the 63 patients with severe brain swelling and coma in the series of Schwab et al, 46 survived and none remained severely disabled. (But there is no question that a number of such patients will remain with hemiplegia.) An anterior temporal lobectomy was performed in addition to the craniotomy in some
cases, but its effect was not clear. The value of surgical decompression has not been limited to patients with right-hemispheric strokes; those with initially limited degrees of aphasia may also be appropriate candidates, but the family must understand the risks involved and the likelihood that the stroke deficits will persist. After a protracted period of coma with bilaterally enlarged pupils or with evidence that the midbrain has been irreversibly damaged, the procedure is probably futile but there have been exceptions. Many in the field remain skeptical of these aggressive approaches, and a randomized trial is under way to settle the issue.

In the special case of large cerebellar infarctions, usually from occlusion of a vertebral artery, swelling may compress the lower brainstem. This type of stroke carries the risk of sudden respiratory arrest. Hydrocephalus usually develops as a prelude to this event and is manifest as drowsiness and stupor, increased tone in the legs, and Babinski signs; other sentinel signs are gaze paresis, sixth nerve palsy, or hemiparesis ipsilateral to the ataxia (Kanis and Ropper). At times it may be difficult to differentiate the effects of increasing hydrocephalus from those of a thrombus propagation in the basilar artery (Lehrich et al). Cerebellar swelling may occur with or without an associated lateral medullary stroke. The situation is comparable to medullary compression caused by cerebellar hemorrhage (page 715). Surgical decompression of the infarcted and swollen tissue should be undertaken almost as soon as cerebellar edema becomes clinically apparent by the emergence of hydrocephalus or brainstem signs, since further swelling can be anticipated. This complication can usually be anticipated in the first 3 or 4 days after a large cerebellar stroke. A brief period of observation before committing to surgery is not unreasonable if the fourth ventricle and peribrainstem cisterns are patent and the patient is awake. Mannitol may be used to prepare the patient for surgery or if a period of observation is anticipated. As in the case of cerebellar hemorrhage, ventricular drainage alone is usually inadequate and, in any case, is unnecessary if the pressure is relieved by craniectomy and resection of infarcted tissue.

**Anticoagulant Drugs** Several considerations weigh in any discussion of the use of anticoagulant treatment of stroke. First is the distinction between anticoagulation to prevent the progression of an acute stroke and the prophylactic use of anticoagulation for the prevention of future strokes after the occurrence of TIAs or an initial stroke. In the latter instance, the pivotal issue is whether the stroke or TIA is atherothrombotic or cardioembolic. As discussed further on, several studies point conclusively to a role for anticoagulation in certain cardioembolic cases, while the indications in atherothrombotic disease are less certain.

Warfarin and heparin have been used extensively to prevent TIAs and reduce the chances of an impending stroke. These anticoagulants may halt the advance of a progressive thrombotic stroke, but they are clearly not effective in all cases and numerous recent studies and position papers have questioned their value altogether (see for example, the Report of the Joint Stroke Guideline Development Committee authored by Coull et al). In deciding whether to use anticoagulants, one faces the question of where in the course of the stroke the patient stands when first examined. One fact seems definite—that the administration of anticoagulants is not of great value once the stroke is fully developed, whether in a patient with a lacunar infarct or one with a massive infarction and hemiplegia. It is as yet uncertain whether the long-term use of anticoagulants prevents the recurrence of a thrombotic stroke; in these cases, the incidence of complicating hemorrhage probably outweighs the value of anticoagulants (atrial fibrillation is an exception—see further on).

The two situations in which the immediate administration of heparin has drawn the most support from our own clinical practice are in fluctuating basilar artery thrombosis and in impending carotid artery occlusion from thrombosis or dissection (see further on). In these situations, the administration of heparin may be initiated while the nature of the illness is being clarified; the drug is then discontinued if contraindicated by new findings. It must be acknowledged that satisfactory clinical studies in support of this approach of acute anticoagulation have not been carried out. The issue of heparinization in cases of recent cardioembolic cerebral infarction is addressed further on in this chapter, under “Embolic Infarction.” However, in anticipation of the later discussion it can again be stated that there is little evidence in support of heparin use in most strokes.

In the event heparin is given, if t-PA has not been used in the preceding 24 h, the heparin may be given intravenously, beginning with a bolus of 100 U/kg followed by a continuous drip (1000 U/h) and adjusted according to the partial thromboplastin time (PTT). Bleeding into any organ may occur when the PTT is much greater than 3 times the pretreatment level. When the PTT exceeds 100 s, it is preferable to discontinue the heparin, check the blood clotting values, and then reinstitute the infusion at a lower rate (rather than simply lower the infusion rate). In circumstances of fluctuating basilar artery ischemia, it has been our practice to permit higher values of PTT.

The use of low-molecular-weight heparin (anti–factor Xa enoxaparin or nadroprin) given subcutaneously within the first 48 h of the onset of symptoms may improve outcome from stroke. In a limited randomized trial, there was no increase in the frequency of hemorrhagic transformation of the ischemic region when compared to placebo treatment (Kay et al). Because the outcome measures in this study were coarse (death or dependence 6 months after stroke), further investigations of this approach need to be carried out. We can only infer that the use of low-molecular-weight heparin (approximately 4000 U subcutaneously, twice daily) appears to be safe and is possibly beneficial.

Whether anticoagulant therapy is effective in preventing strokes in patients with TIAs or recent stroke is a question that has never been answered satisfactorily. Swanson has reviewed several trials evaluating heparin (including the International Stroke Trial and the TOAST study) and suggested that there was no net benefit from heparin in acute stroke because of an excess of cerebral hemorrhages. However, there was in these series a low incidence, estimated as 2 percent, of recurrent stroke in the first weeks after a cerebral infarction in the untreated groups. An early recurrent stroke rate this low almost precludes demonstrating a benefit from the use of heparin or heparinoid drugs.

The long-term use of warfarin following atherothrombotic stroke is also still under critical analysis. To date it seems to be of some slight value in the prevention of further thrombosis and embolism. There are data to suggest that the greatest usefulness of warfarin is in the first 2 to 4 months following the onset of ischemic attack(s); after that time the risk of intracranial hemorrhage may exceed the benefits of anticoagulant therapy (Sandok et al). However, in comparison to aspirin, discussed below, there is no reason to favor warfarin in cases of atherothrombotic stroke. This was amply shown in the so-called WARSS study (not including cardioembolic stroke) published by Mohr and colleagues (2001); over 2 years the recurrent stroke rate was about 16 percent in both groups.
and, surprisingly the rate of cerebral hemorrhage was similar (near 2 percent). In contrast to the situation with atherothrombotic disease, warfarin has been found to be superior for prevention of a second stroke in cardioembolic disease, as discussed further on.

Of course, the use of anticoagulant drugs makes an accurate diagnosis imperative. Intracranial hemorrhage must be excluded by CT scan. An estimation of prothrombin and partial thromboplastin activity is needed before therapy is started, but if this is not feasible, the initial doses of anticoagulant drugs can usually be given safely if there is no clinical evidence of bleeding anywhere in the body and there has been no recent surgery. Warfarin therapy, beginning with a dose of 5 to 10 mg daily, is relatively safe provided that the international normalized ratio (INR) is brought to 2 to 3 (formerly measured as a prothrombin time between 16 and 19 s) and the level is determined regularly (once a day for the first 5 days, then two or three times a week for a week or two, and finally once every several weeks). There is no reliable evidence that complications are more frequent in the presence of hypertension if the INR is not allowed to exceed two to three times normal; therefore the authors have not withheld anticoagulant therapy in these patients. However, when the blood pressure is greater than 220/120 mmHg, an attempt is made to lower it gradually at the same time. Numerous drugs may alter the anticoagulant effects of the coumarins or add to the risk of bleeding — aspirin, cholestyramine, alcohol, barbiturates, carbamazepine, cephalosporin and quinolone antibiotics, sulfa drugs, and high-dosage penicillin being the most important ones. The INR must be determined regularly if the administration of warfarin is necessary. Hemorrhagic skin necrosis is a rare but dangerous complication. It is due to a paradoxical microthrombosis of skin vessels and is liable to occur in patients with unsuspected deficiencies of endogenous clotting proteins (S and C). Although the disseminated form of skin necrosis occurs within days of initiating warfarin therapy, we have seen one patient with a form of this lesion following local skin injury after months on treatment.

Any type of serious bleeding from warfarin overdosage demands immediate administration of fresh plasma and large doses of vitamin K. An INR above 5 in a patient who must remain anticoagulated — for example, one with a prosthetic heart valve — may be corrected with small doses of vitamin K (0.5 to 2 mg), preferably given intravenously.

The problem that continues to plague all attempts to use long-term anticoagulants, as already noted for heparin in the acute situation, is the risk of hemorrhage, which approaches 10 percent, with a mortality of 1 percent. The risk of intracranial hemorrhage has been estimated by Whisnant and colleagues to be 5 percent for warfarin and 3 percent for heparin. The risk is considerably higher in elderly patients who have been treated for more than 1 year. Thus, it would appear that with long-term administration of anticoagulants, except in certain circumstances — such as a severely stenotic cerebral vessel, atrial fibrillation, prosthetic heart valve, or certain blood disorders — the risk of hemorrhage outweighs the benefit from prevention of stroke.

**Antiplatelet Drugs**  
Aspirin (325 mg daily) has proved to be perhaps the most consistently useful drug in the prevention of thrombotic and embolic strokes. One currently favored approach, based in part on the above-mentioned WARSS trial, is to simply administer aspirin in all cases of acute stroke (except perhaps if t-PA has been used). The acetyl moiety of aspirin combines with the platelet membrane and inhibits platelet cyclooxygenase, thus preventing the production of thromboxane A$_2$, a vasoconstricting prostaglandin, and also prostacyclin, a vasodilating prostaglandin. In patients who cannot tolerate aspirin, the platelet aggregate inhibitor clopidogrel or a similar drug (such as ticlopidine or dipyridamole) can be substituted (see below).

A number of controlled studies have attested to the therapeutic value of aspirin and ticlopidine, clopidogrel, or dipyridamole, but it is important not to exaggerate the magnitude of their effects. These studies have been critically reviewed by Tijssen and by Algra and colleagues. With few exceptions, it can be concluded that aspirin is beneficial in preventing stroke; whether low doses (50 to 100 mg) and high doses (1000 to 1500 mg) provide equivalent protection is still uncertain. From a review of these studies, it appears that both dosages are effective and that the addition of dipyridamole further reduces the risk of stroke by a small amount. Ticlopidine and clopidogrel are believed by some, on the basis of clinical trials, to be marginally more effective than aspirin for the prevention of stroke, but they are far more expensive, and ticlopidine is potentially toxic (neutropenia). Dipyridamole in high doses has not been as well tolerated by our patients because of induced dizziness. The combined use of these drugs with aspirin has not been extensively examined, but recent data from the PROFESSION trial (Prevention Regimen for Effectively Avoiding Second Strokes) has suggested that there may be an increased risk of cerebral hemorrhage when aspirin is combined with clopidogrel; our patients have not experienced such events, but perhaps the combination should be used with caution.

These studies notwithstanding, the therapeutic effectiveness of aspirin is still rather slight. The cumulative evidence from trials with aspirin alone indicates that a dose of aspirin of at least 30 mg/day reduces by 13 percent, at most, the progression or recurrence of stroke (Algra et al). Moreover, in each of the trials, a significant number of subsequent ischemic strokes occurred in patients while they were receiving aspirin.

The best course of treatment for patients who have lacunar or atherothrombotic strokes while already receiving antiplatelet medications is not clear. Control of blood pressure and the administration of a lipid-lowering drug is advisable, even if lipid levels are normal. Switching to warfarin from anti-platelet agents is sensible in some circumstances but should be done with caution.

**Other Forms of Medical Treatment**  
Treatment by hemodilution was popularized by the studies of Wood and Fleischer, who showed a high incidence of short-term improvement when the hematocrit was reduced to approximately 33 percent. That lowering blood viscosity improves regional blood flow in the heart had been known for some time, and a similar effect on the brain has been demonstrated by CBF studies. Earlier observations had shown a reduction in the overall neurologic deficit, but almost all larger randomized trials — which included patients in many settings who were treated at various times up to 48 h after stroke — failed to confirm any such benefit, and the use of this treatment has been virtually abandoned. Nevertheless, we continue to see a few patients whose hemiparesis and aphasia have improved during and just after removal of a unit or more of blood and replacement with albumin and saline. While this treatment cannot be recommended as a routine approach, it may have some merit in selected situations, such as fluctuating stroke. Therapies aimed at improving blood flow by enhancing cardiac output (aminophylline, pressor agents), by improving the microcirculation (mannitol, glycerol, dextran), or by use of a large number of vasodilating drugs (see below) have failed to show consistent benefits, but several are still under study.
Hyperbaric oxygen may reduce ischemic deficits temporarily but has no sustained effect. Induced hypothermia limits the size of ischemic stroke, but it is technically difficult to administer and often has serious side effects.

Calcium channel blockers of the types administered for cardiac disease have also been found to increase CBF and to reduce lactic acidosis in stroke patients. However, several multicenter clinical trials that compared calcium channel blockers with placebo did not establish a difference in outcome in the two groups. There has also been interest, as noted earlier in this chapter, in drugs that inhibit excitatory amino acid transmitters and free-radical scavengers such as dimethyl sulfoxide (DMSO) and growth factors, but so far none of these has been successfully applied to humans.

Despite some experimental evidence that certain vasodilators, such as CO₂ and papaverine, increase CBF, none has proved beneficial in carefully studied human stroke cases at the stage of TIAs, thrombosis in evolution, or established stroke. Vasodilators may actually be harmful, at least on theoretical grounds, since by lowering the systemic blood pressure or dilating vessels in normal brain tissue (the autoregulatory mechanisms are lost in vessels within the infarct), they may reduce the intracranial anastomotic flow. Moreover, the vessels in the margin of the infarct (border zone) are already maximally dilated. New discoveries regarding the role of nitric oxide in vascular control will probably give rise to new pharmacologic agents, which will have to be evaluated.

**Surgery and Angioplasty for Symptomatic Carotid Stenosis**

Comments have already been made concerning the opening of an occluded carotid artery soon after a stroke. Here we discuss the patient who has passed the acute period, when surgery is safer, or who has TIA. The region that most often lends itself to such therapy is the carotid sinus (the bulbous expansion of the internal carotid artery just above its origin from the common carotid). Other sites suitable for surgical management include the common carotid, innominate, and subclavian arteries. Operation on the vertebral artery at its origin has proved successful only in exceptional circumstances. In recent years balloon angioplasty and stenting of the carotid artery have become increasingly popular as an alternative to surgery (see below).

Surgery and angioplasty, in our opinion, are as yet applicable mainly to the group of patients with *symptomatic* carotid artery stenosis (the asymptomatic ones are discussed below) who have substantial extracranial stenosis but not complete occlusion, and, in special instances, in those with nonstenotic ulcerated plaques. Those with stenosis constitute less than 20 percent of all patients with TIA (Marshall); but from the perspective of surgical therapy, the term *symptomatic* encompasses both TIA and small strokes ipsilateral to the stenosis. There is now convincing evidence that well-executed surgery in appropriately chosen cases arrests the TIA and diminishes the risk of future strokes. These views have received strong affirmation from two well-designed randomized studies—the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST). The conclusion, reached in each of these studies, was that carotid endarterectomy for symptomatic lesions causing severe degrees of stenosis (>70 to 80 percent reduction in diameter) is effective in reducing the incidence of ipsilateral hemispheric strokes. These two trials differed in the method of estimating the degree of stenosis, but when adjustments are made, the results are comparable (Donnan et al). Patients in the European study with mild or moderate stenosis (up to 70 percent) did not benefit from endarterectomy. In the North American study, however, they did so, but to a lesser extent than the group with severe stenosis. Further analysis of the North American trial by Gasecki and colleagues has indicated that the risk of cerebral infarction on the side of the symptomatic stenosis is increased if there is a contralateral carotid stenosis but that operated patients (on the side of symptomatic stenosis) still had fewer strokes than those treated with medication alone. In those with bilateral carotid disease, the risk of stroke after 2 years was 69 percent, and if operated, 22 percent. In the final analysis, the relative benefits of surgery or medical treatment (anticoagulation or aspirin) depend mainly on the true surgical risk—i.e., on the record of an individual surgeon. If the surgeon, by an independent audit of his procedures, has an established operative complication rate of no more than 4 to 5 percent and preferably lower, then surgery can be recommended in symptomatic patients with carotid stenosis greater than 70 percent. This benefit extends to elderly patients and, indeed, it has been shown on a statistical basis to be most evident in patients over age 75 (see the reanalysis of NASCET data by Alomamowitch and colleagues).

Before operation or angioplasty, the existence of the lesion and its extent must be determined. Arteriography, the procedure that yields the best images and most accurate measurements of the residual lumen, carries a very small risk of worsening the stroke or producing new focal signs (this notion has never been documented systematically). Severe stenosis is reflected in conventional angiography by the filling of the distal branches of the external carotid artery before the branches of the middle cerebral artery are opacified—a reversal of the usual filling pattern, indicating low flow in the distal carotid circulation. Increasingly the diagnosis of carotid stenosis is being made by noninvasive methods, but with both ultrasound and magnetic resonance arteriography, there is difficulty in quantifying severe stenosis and separating it from complete carotid artery occlusion. Perfusion CT imaging may provide a more accurate alternative at low risk (the volume of dye required may still be prohibitive in patients with renal failure).

If the patient is in good medical condition, has normal vessels on the contralateral side, and has normal cardiac function (no heart failure, uncontrolled angina, or recent infarction), these lesions can usually be dealt with safely by endarterectomy. The procedure is not, however, innocuous. It may be followed by a new hemi/pa/ or aphasia that becomes evident immediately or soon after endarterectomy, usually by the time the patient arrives in the recovery room. In general, surgeons prefer to return the patient to the operating room and open the artery, as discussed earlier on. An internal flap at the distal end of the endarterectomy and varying amounts of fresh clot proximal to it are usually encountered; but after removal and repair of the vessel, the effects of the stroke, if one has occurred, are not usually improved.

An uncommon but rather striking *hyperperfusion syndrome* develops several days to a week after carotid endarterectomy. The features are headache, focal deficits, seizures, brain edema, or cerebral hemorrhage; these are thought to reflect an abrupt loss of autoregulatory ability of the cerebral vasculature in the face of hypertension and increased perfusion on the side of the recently opened artery. Unilateral severe headache is the commonest symptom and may be the only manifestation. On occasion the cerebral edema is so massive as to lead to death (Breen et al). Treatment is by control of hypertension; it is unclear whether anticonvulsant medications are required if there has been a single seizure, but they seem valuable to us. We mention here that an identical syndrome of focal cerebral deficits and brain edema, perhaps with the excep-
Asymptomatic Carotid Stenosis

Finally, there is the problem of the asymptomatic carotid bruit or incidentally discovered stenosis. The population study by Heyman and associates has shed some light on this. They found, not surprisingly, that cervical bruits in men constituted a risk for death from ischemic heart disease. They also noted that the presence of asymptomatic bruits in men (but not in women) did carry a slightly increased risk of stroke but, more importantly, that the subsequent stroke often did not coincide in its angioanatomic locus and laterality with the cervical bruit. Similar findings have been reported by Ford and coworkers and by Chambers and Norris. On the other hand, Wiebers and colleagues found that patients with asymptomatic carotid bruits who were followed for 5 years were approximately three times more likely to have ischemic strokes than an age- and sex-matched population sample without carotid bruits.

In an attempt to clarify the role of surgery for asymptomatic carotid stenosis, the Asymptomatic Carotid Atherosclerotic Study (ACAS), as reported by their Executive Committee, has suggested that the frequency of strokes can be reduced from 11 to 5 percent over 5 years by removing the plaque in asymptomatic patients in whom there is a stenosis greater than 60 percent (diameter). These findings have been tempered by a reanalysis of the ACAS data, pointing out that almost half of the strokes in these patients were lacunar or cardioembolic in origin (Inzitari et al). Data from a recent European trial, encompassing 3120 patients, obtained similar results [MRC Asymptomatic Carotid Surgery Trial (ACST) Collaborative Group]. The latter study has indicated that asymptomatic carotid stenosis of over 50 percent carries only a 2 percent annual risk of stroke over a 5-year period and that the risk is reduced to less than 1 percent with endarterectomy. It was concluded that endarterectomy may be justified for asymptomatic carotid stenosis of this degree, but the authors emphasized that an audited surgical risk is still being determined, but it offers an alternative to surgery if the patient is too ill to undergo an endarterectomy. Direct comparisons are being made to surgery in several organized studies. In one randomized trial reported by the CAVATAS investigators, the incidence of minor (nonstroke) complications was lower in patients who had angioplasty and stenting. This has not been our experience, where sizable groin hematomas have been common. Also, a higher proportion of these patients than those who had undergone endarterectomy had restenosis. Otherwise, the recurrent stroke rates were similar, 10 percent for both groups.

Asymptomatic Carotid Stenosis

The benefits of surgery for asymptomatic carotid stenosis seem to us to be marginal and we counsel caution until more definite data on this matter have been obtained. Also, as already noted, the neurologist’s advice should be tempered by the documented surgical risk in his particular institution. Our practice with asymptomatic cases has been to re-evaluate the lumen of the internal carotid artery (by ultrasound) at 6- to 12-month intervals. Only if the lumen is decreasing in size and becomes narrowed to 1.5 mm or less or if there is an event that could be construed as a TIA referable to the stenotic side is surgery considered. In the case of an asymptomatic but progressive stenosis larger than 1.5 mm, there is still considerable controversy about treatment; anticoagulation or antiplatelet agents are reasonable alternatives to surgery.

We generally agree with the guidelines for carotid endarterectomy set down by the American Heart Association as reported by Moore and colleagues, but there must be a careful evaluation of the circumstances in each patient.

Physical Therapy and Rehabilitation

In all but the most seriously ill patients, beginning within a few days of the stroke, the paralyzed limbs should ideally be carried through a full range of passive movement several times a day. The purpose is to avoid contracture (and periartthritis), especially at the shoulder, elbow, hip, and ankle. Soreness and aching in the paralyzed limbs should not be allowed to interfere with exercises. Patients should be moved from bed to chair as soon as the stroke is completed and blood pressure is stable. Prophylaxis for deep venous thrombosis is appropriate if the patient cannot be mobilized. An assessment for swallowing difficulty should be made early during recovery and dietary adjustments made if there is a risk of aspiration. Nearly all hemiplegics regain the ability to walk to some extent, usually within a 3- to 6-month period, and this should be a primary aim in rehabilitation. The presence of deep sensory loss or anosognosia in addition to hemiplegia is the main limiting factor. A short or long leg brace is often required. By teaching patients with cerebellar ataxia new strategies, balance and gait disorders can be made less disabling. As motor function improves and if mentality is preserved, instruction in the activities of daily living and the use of various special devices can help the patient to become at least partly independent in the home. What little research is available on the effectiveness of stroke rehabilitation suggests that a greater intensity of physical therapy does indeed achieve better scores on some measures of walking ability and dexterity. In a randomized trial, Kwakkel and colleagues achieved these results by applying an additional 30 min per day beyond conventional physical therapy of focused treatments to the leg or arm, 5 days per week, for 20 weeks. Other studies have demonstrated clearly the now well-known undesirable effects of immobilizing a limb in a splint after a stroke.

The neural substrates of improvement after stroke are just beginning to be studied. A wealth of clinical experience and physiologic and radiographic data have demonstrated that the injured brain has some degree of plasticity; remodeling of brain tissue and reorganization of neural function continue for months after even large motor deficits. Experimental work in monkeys and limited data from patients suggest that improvement can be obtained by restraining the normal limb and forcing use of the sound limb. This may reflect functional expansion of the cortical motor representation into adjacent undamaged cortical areas, indicating the potential...
for some degree of reorganization that corresponds to clinical recovery.

Speech and language therapy are particularly valuable in identifying the risk of aspiration as noted above. Specific therapy should be given in appropriate cases, and certainly improves the morale of the patient and family. Further comments on the value of such therapy can be found in Chap. 23, on language disturbances.

**Preventive Measures** Since the primary objective in the treatment of atherothrombotic disease is prevention, efforts to control the risk factors must continue. The carotid vessels, being readily accessible, must always be examined for the presence of a bruit; the latter quite reliably indicates a stenosis, though not all stenoses cause a bruit and some bruits heard bilaterally are transmitted sounds from a stenotic aortic valve. Ultrasound examination of the carotid is justified in almost all patients with TIAs and ischemic stroke. While a self-audible bruit occasionally indicates carotid stenosis, dissection, or fibromuscular dysplasia, it is usually benign and in some instances associated with an enlarged, superiorly displaced jugular bulb—a benign anatomic variant that can be discerned on CT scan (Adler and Ropper). Other instances are attributable to raised intracranial pressure (pseudotumor cerebri). The management of patients with asymptomatic carotid bruits has been considered above.

For patients who have had a stroke from atherothrombotic disease and are functional, preventive measures consist of reducing the future occurrence of strokes. Such measures include the following: (1) aspirin—which has been shown to reduce the risk of second stroke slightly, but its effect, as already noted, should not be overestimated (see page 697); (2) any required antihypertensive agents—whether given therapeutically or for diagnostic procedures, should be administered with caution; (3) cholesterol-lowering drugs should be administered unless the cholesterol level is already low or there is a contraindication; (4) smoking cessation is mandatory and the patient should be supported in such efforts; and (5) particular care should be taken to maintain the systemic blood pressure, oxygenation, and intracranial blood flow during general surgical procedures, especially in elderly patients.

The ultimate solution of the problems of ischemic infarction and TIAs lies in more fundamental fields—namely, the prevention or alleviation of hypertension and atherosclerosis.

**Emolic Infarction**

As already stated, this is the *commonest cause of stroke*. The characteristic feature is the abrupt onset of a focal neurologic deficit. In most cases of cerebral embolism, the embolic material consists of a fragment that has broken away from a thrombus within the heart. Somewhat less frequently the source is intra-arterial, from the distal end of a thrombus within the lumen of an occluded or severely stenotic carotid or vertebral artery or the distal end of a carotid dissection, or possibly from an atheromatous plaque that has ulcerated into the lumen of the carotid sinus. Single or sequential emboli may also arise from large atheromatous plaques in the ascending aorta. Thrombotic or infected material (endocarditis) that adheres to the aortic or mitral heart valves and break away are also well appreciated sources of embolism. Embolism due to fat, tumor cells (atrial myxoma), fibrocartilage, amniotic fluid, or air seldom enters into the differential diagnosis of stroke except in special circumstances.

The embolus usually becomes arrested at a bifurcation or other site of natural narrowing of the lumen of an intracranial vessel, and ischemic infarction follows. The infarction is pale, hemorrhagic, or mixed; hemorrhagic infarction nearly always indicates embolism, though most are pale. Any region of the brain may be affected, the territory of the middle cerebral artery, particularly the superior division, being the most frequently involved. The two cerebral hemispheres are approximately equally affected. Large embolic clots can block large vessels (sometimes the carotids in the neck or at their termination intracranially), while tiny fragments may reach vessels as small as 0.2 mm in diameter usually with consequential effects. The embolic material may remain arrested and plug the lumen solidly, but more often it breaks into fragments that enter smaller vessels and disappear, so that even careful pathologic examination fails to reveal their final location. In this instance, the clinical effects may clear in hours. The anatomic diagnosis must then be made by inference, e.g., absence of a vascular occlusion at the proper site to explain the infarct; absence of atherosclerosis or other cause of occlusion in the offending cerebral vessel; presence of a source of embolii, atrial fibrillation, or infarcts in other organs such as the kidneys and spleen; the occurrence of hemorrhagic infarction; and finally the clinical history, which is characterized by an absolutely abrupt onset, as described below.

Because of the rapidity with which embolic occlusion develops, there is no much time for collateral influx to become established. Thus, sparing of the territory distal to the site of occlusion is not as evident as in thrombosis. However, the vascular anatomy and ischemia-modifying factors mentioned above, under “The Ischemic Stroke,” are still operative and influence the size and magnitude of the infarct.

Brain embolism is predominantly a manifestation of heart disease, and fully 75 percent of cardiogenic emboli lodge in the brain. The commonest identifiable cause is chronic or recent atrial fibrillation, the source of the embolus being a mural thrombus within the atrial appendage (Table 34-7). Patients with chronic atrial fibrillation are about six times more liable to stroke than age-matched population with normal cardiac rhythm (Wolf et al) and the risk is considerably higher if there is also rheumatic valvular disease as mentioned earlier. Furthermore, the risk conferred by the presence of atrial fibrillation varies with age, being 1 percent per year in persons younger than 65, and as high as 8 percent per year in those over 75 with additional risk factors. These levels of risk are of prime importance in determining the advisability of anticoagulation, as discussed below. Embolism may also occur during paroxysmal atrial fibrillation or flutter. Mural thrombus deposited on the damaged endocardium overlying a myocardial infarct in the left ventricle, particularly if there is an aneurysmal sac, is an important source of cerebral emboli, as is a thrombus associated with severe mitral stenosis without atrial fibrillation. Emboli tend to occur in the first few weeks after an acute myocardial infarction, but Loh and colleagues found that a lesser degree of risk persists for up to 5 years. Cardiac catheterization or surgery, especially valvuloplasty, may disseminate fragments from a thrombus or a calcified valve. Mitral and aortic valve prostheses are additional important sources of embolism.

Another source of embolism is the carotid or vertebral artery, where clot forming on an ulcerated atheromatous plaque may be detached and carried to an intracranial branch (artery-to-artery embolism). A similar phenomenon may occur with arterial dissections and sometimes with fibromuscular disease of the carotid or vertebral arteries.

*Atheromatous plaques in the ascending aorta* have been rec-
Table 34-7
Causes of cerebral embolism

1. Cardiac origin
   a. Atrial fibrillation and other arrhythmias (with rheumatic, atherosclerotic, hypertensive, congenital, or syphilitic heart disease)
   b. Myocardial infarction with mural thrombus
   c. Acute and subacute bacterial endocarditis
   d. Heart disease without arrhythmia or mural thrombus (mitral stenosis, myocarditis, etc.)
   e. Complications of cardiac surgery
   f. Valve prostheses
   g. Nonbacterial thrombotic (marantic) endocardial vegetations
   h. Prolapsed mitral valve
   i. Paradoxical embolism with congenital heart disease (e.g., patent foramen ovale)
   j. Myxoma

2. Noncardiac origin
   a. Atherosclerosis of aorta and carotid arteries (mural thrombus, atheromatous material)
   b. From sites of dissection and/or fibromuscular dysplasia of carotid and vertebralbasilar arteries
   c. Thrombus in pulmonary veins
   d. Fat, tumor, or air
   e. Complications of neck and thoracic surgery
   f. Pelvic and lower extremity venous thrombosis in presence of right-to-left cardiac shunt

3. Undetermined origin

Oxidized in the last decades to be a more frequent source of embolism than had been appreciated. Amanenco and colleagues reported that as many as 38 percent of a group of patients with no discernible cause for embolic stroke had echogenic atherosclerotic plaques in the aortic arch that were greater than 4 mm in thickness, a size thought to be associated on a statistical basis with strokes. Disseminated cholesterol emboli are known to occur in the cerebral circulation and may be dispersed in other organs as well; rarely, this is sufficiently severe to cause an encephalopathy and pleocytosis in the spinal fluid.

Paradoxical embolism can occur when an abnormal communication exists between the right and left sides of the heart (particularly a patent foramen ovale, or PFO) or when both ventricles communicate with the aorta; thus embolic material arising in the veins of the lower extremities or pelvis or elsewhere in the systemic venous circulation can bypass the pulmonary circulation and reach the cerebral vessels. Pulmonary hypertension (often from previous pulmonary embolism) favors the occurrence of paradoxical embolism, but this may occur with a PFO even in the absence of pulmonary hypertension. Of 30 patients in whom a PFO could be demonstrated, 17 had evidence of a right-to-left shunt; brain infarction was associated with positive phlebography of the legs and abnormal pulmonary scintigraphy (Itoh et al.). Several studies indicated that the presence of a small atrial septal aneurysm adjacent to the patent foramen increases the likelihood of stroke. In the series of Mas and colleagues, patients ages 18 to 55 who had a stroke were followed for 4 years; the risk of second stroke was 2 percent in those with a PFO alone and 15 percent among those with both a PFO and an atrial septal aneurysm (curiously, the risk among those with neither congenital abnormality was 4 percent—higher than for PFO). This mechanism comes into play mainly in considering the causes of stroke in the younger patient. Subendocardial fibroelastosis, idiopathic myocardial hypertrophy, cardiac myxomas, and cardiac lesions of trichinosis are rare causes of embolism.

The vegetations of acute and subacute bacterial endocarditis give rise to several different lesions in the brain (page 606). Mycotic aneurysm is a rare complication of septic embolism and may be a source of intracerebral or subarachnoid hemorrhage. Marantic or nonbacterial thrombotic endocarditis is a frequently overlooked cause of cerebral embolism; at times it produces a baffling clinical picture, especially when associated, as it often is, with carcinomatosis, cachexia from any cause, or lupus erythematosus. This subject is discussed on page 735.

Mitrval valve prolapse may be a source of emboli, especially in young patients, but its importance has probably been overestimated. The initial impetus for considering this abnormality as a source of embolus came from the study of Barnett and colleagues of a group of 60 patients who had TIAs or partial strokes and were under 45 years of age; prolapse was detected (by echocardiography and a characteristic midsystolic click) in 24 patients but in only 5 of 60 age-matched controls. However, in several subsequent large studies (Sandok and Giuliani and Jones et al), only a very small proportion of strokes in young patients could be attributed to prolapse; even then, the connection was only inferred by the exclusion of other causes of stroke. Indeed, in a recent study using stringent criteria for the echocardiographic diagnosis of prolapse, Gilon and colleagues could not establish any relation to stroke. Rice and colleagues have described a family with premature stroke in association with valve prolapse and a similar relationship has been reported in twins; the same may occur in Ehlers-Danlos disease.

The pulmonary veins are a potential if infrequent source of cerebral emboli, as indicated by the occurrence of cerebral abscesses in association with pulmonary suppurative disease and by the high incidence of cerebral deposits secondary to pulmonary carcinoma. In Osler-Weber-Rendu disease, pulmonary shunts serve as a conduit for emboli. As remarked above, surgery of the neck and thorax can be complicated by cerebral embolism. A rare type is that which follows thyroidectomy, where thrombosis in the stump of the superior thyroid artery extends proximally until a section of the clot, protruding into the lumen of the carotid, is carried into the cerebral arteries.

During cerebral arteriography, emboli may arise from the tip of the catheter, or manipulation of the catheter may dislodge atheromatous material from the aorta or carotid or vertebral arteries and account for some of the accidents during this procedure. Transcranial Doppler isonation has suggested that small emboli frequently arise during these procedures; a study by Bendszus and colleagues found that 23 of 100 consecutive patients had new cortical lesions shown on diffusion-weighted MRI just after cerebral arteriography. However, none of these were symptomatic and with good technique, emboli from vascular catheters are infrequent.

Cerebral embolism must always have occurred when secondary tumor is deposited in the brain, and cerebral embolism regularly accompanies sepsisemia, but a mass of tumor cells or bacteria is seldom large enough to occlude a cerebral artery and produce the picture of stroke. Nevertheless, tumor embolism with stroke has been reported from cardiac myxomas and occasionally with other tumors. It must be distinguished from embolism due to marantic endocarditis that complicates malignant neoplasms (nonbacterial thrombotic endocarditis, discussed further on). Cerebral fat embolism is related to severe bone trauma. As a rule, the emboli are
minute and widely dispersed, giving rise first to pulmonary symptoms and then to multiple dermal (anterior axillary fold and elsewhere) and cerebral petechial hemorrhages. Accordingly, the clinical picture is more of an encephalopathy and not strictly focal, as it is in a stroke, although in some instances it may have focal features. Cerebral air embolism is a rare complication of abortion, scuba diving, or cranial, cervical, or thoracic operations involving large venous sinuses; it was formerly encountered as a complication of pneumothorax therapy. Clinically, this condition may be difficult to separate from the deficits following hypotension or hypoxia, which frequently coexist. Hyperbaric treatment may be effective if instituted early.

Despite the large number of established sources of emboli, the point of origin cannot be determined in about 30 percent of presumed embolic infarctions. In such cases, emboli may have originated from thrombi in the cardiac chambers but have left behind no residual clot and may be undetectable by even sophisticated methods such as transeosophageal echocardiography and newer MR techniques. Others may be due to atheromatous material arising from the aorta. If extensive evaluation fails to disclose the origin, the odds still favor a source in the left heart. Not infrequently the diagnosis of cerebral embolism is made at autopsy without finding a source. The search for a thrombotic nidus may not have been sufficiently thorough in these cases, and small thrombi in the atrial appendage, endocardium (between the papillary muscles of the heart), the aorta and its branches, or pulmonary veins may have been overlooked. Nevertheless, in some cases, even when studied carefully postmortem, no source of embolic material can be discovered.

Clinical Picture Of all strokes, those due to cerebral embolism develop most rapidly, “like a bolt out of the blue.” As a rule, the full-blown picture evolves within seconds, exemplifying most strikingly the temporal profile of a stroke. With rare exceptions, there are no warning episodes. The embolus strikes at any time of the day or night. Getting up to go to the bathroom is a time of danger. Only occasionally and for unclear reasons, the clinical picture unfolds more gradually, over many hours, with some fluctuation of symptoms. Possibly, in these cases, the embolus initiates a thrombotic process in the occluded vessel.

The neurologic picture will depend on the artery involved and the site of obstruction. The syndromes related to each angioanatomic territory are the same as those outlined earlier in this chapter, under “Neurovascular Syndromes.” A large embolus may plug the distal internal carotid artery or the stem of the middle cerebral artery, producing the full-blown syndromes that follow occlusion of these arteries. More often the embolus passes into one of the branches of the middle cerebral artery, producing a strikingly focal disorder such as a motor speech disorder, a monoplegia, or a receptive type of aphasia. Any fragment of the middle cerebral syndrome or the complete picture may occur; the same is true for the anterior and posterior cerebral arteries, which are affected at a lower frequency than the middle cerebral because of their lower rates of blood flow.

Embolic material entering the vertebrobasilar system occasionally stops in the vertebral artery just below its union with the basilar; more often it traverses the vertebral and also the basilar artery, which is longer, and is not arrested until it reaches the upper bifurcation, where it produces the abrupt onset of coma and total paralysis or one of the related “top of the basilar” syndromes, described earlier in the chapter. Or the embolus may enter one or both posterior cerebral arteries and, by infarction of the visual cortex, cause unilateral or bilateral homonymous hemianopia. The medial temporal lobe or thalamus and subthalamus may be affected as a consequence of occlusion of the temporal branches or of small penetrating vessels that arise from the posterior cerebral artery, resulting in a number of disorders of memory, sensation, and movement. Embolic infarction of the undersurface of the cerebellum is not infrequent (Figs. 34-1 and 34-19); in addition to ataxia, there are often telltale signs of posterior medullary ischemia. Embolic material rarely enters the penetrating branches of the pons.

It is important to repeat that an embolus may produce a severe neurologic deficit that is only temporary; symptoms disappear as the embolus fragments. In other words, embolism is a common cause of a single evanescent stroke that may reasonably be called a prolonged TIA. Also, as already pointed out, several emboli can give rise to multiple scattered infarcts or two or three transient attacks of differing pattern or, rarely, of almost identical pattern.

Also of interest are the symptoms caused by an embolus as it traverses a large vessel as mentioned on page 688. This “migrating, or traveling, embolus syndrome” is most evident in cases of posterior cerebral artery occlusion, either from a cardiogenic source or from a thrombus in the vertebral artery (“artery-to-artery” embolism; see Koroshetz and Ropper). Minutes or more before the hemianopia develops, the patient may report fleeting dizziness or vertigo, diplopia, or dysarthria, the result of transient occlusion of the origins of small penetrating vessels as the embolus traverses the basilar artery. Small residual areas of infarction within the brainstem or cerebellum can be seen on MRI or found at autopsy and some of the signs of brainstem infarction may persist.

Figure 34-19. Early inferior cerebellar cortical infarction (arrowhead). T2-weighted MRI showing the lesion which encompasses the surface of the cerebellum and the immediately underlying tissue, typical of an embolic stroke, in the territory of the right posterior inferior cerebellar artery. There is a small infarction on the undersurface of the left cerebellum as well, further indicative of embolism.
Although the abruptness with which the stroke develops and the lack of prodromal symptoms point strongly to embolism, the diagnosis is based on the total clinical picture. As already emphasized, the presence of atrial fibrillation, a history of myocardial infarction (recent or in the preceding months), cardiac valvular disease or a prosthetic valve, or the occurrence of embolism to other vascular territories of the brain or to other regions of the body all support the diagnosis of embolism. This diagnosis always merits careful consideration in young persons, in whom atherosclerosis is unlikely. In instances in which the cause of embolisms cannot be ascertained, the practice is nevertheless to class them as thromboembolic.

**Laboratory Findings** Not infrequently the first sign of myocardial infarction is the occurrence of cerebral embolism; therefore it is advisable that an ECG and echocardiogram be obtained in all patients with stroke of uncertain origin, particularly since about 20 percent of myocardial infarctions are of the “silent” variety; if the ECG does not yield relevant information, prolonged study of heart rhythm with Holter monitoring should be undertaken. Also, as indicated earlier, it is advisable in the elderly or in patients with severe atherosclerosis to image the aortic arch with ultrasound or MRA, looking for plaques greater than 4 mm in thickness (Amaral et al).

Transesophageal echocardiography, which has a higher sensitivity than transthoracic echocardiography, is an important test in the evaluation of stroke in younger patients, in whom a PFO may be a mechanism for paradoxical embolism, and in older patients with arteriopathy, in whom an atrial clot or an aortic plaque may be responsible. In a study of 824 patients at the Cleveland Clinic (Leung and associates), transesophageal echocardiography detected a potential source of embolism in 50 percent, an atrial clot in 7 percent, and a complex aortic atheroma in 13 percent of those with normal transthoracic studies. The precise indications for this test, however, have not been clearly determined, and various studies give widely varying estimates of its usefulness in detecting a cardiac thrombus.

In some 30 percent of cases, cerebral embolism produces a hemorrhagic infarct. CT scanning or MRI may be helpful in showing the more extensive hemorrhagic infarcts, particularly if the scan is repeated on the second or third day or later. Only in a minority of these instances do red cells enter the CSF—rarely as many as 10,000/mm³. In the milder cases of hemorrhagic infarction, a slight xanthochromia may appear after a few days.

Septic embolism resulting from *subacute bacterial endocarditis* may cause the white blood cells (WBCs) in the CSF to be increased, up to 200/mm³ but occasionally much higher; the proportion of lymphocytes and polymorphonuclear cells varies with the acuteness of the inflammatory reaction. There may also be an equal number of red blood cells and a faint xanthochromia. The protein content is elevated but the glucose content is normal. However, no bacteria are seen or obtained by culture. By contrast, the protein content is elevated but the glucose content is normal. How-equal number of red blood cells and a faint xanthochromia. The portion of lymphocytes and polymorphonuclear cells varies with

**Course and Prognosis** The remarks concerning the immediate prognosis of atherothrombotic infarction apply to embolic infarction as well. Most patients survive the initial insult, and in many the neurologic deficit may recede relatively rapidly, as indicated above. Progressive brain swelling occurs in a small proportion, less than 5 percent, and mainly in patients with embolic occlusion of the distal carotid or the stem of the middle cerebral artery and in a larger proportion of sizable cerebellar infarcts. In the case of massive cerebral edema, management follows along the same lines as that for atherosclerotic thrombotic infarction (page 695). The eventual prognosis is determined by the occurrence of further emboli and the gravity of the underlying illness—cardiac failure, myocardial infarction, bacterial endocarditis, malignancy, and so on.

In a small number of cases, the first episode of cerebral embolism will be followed by another, frequently with severe consequences if the second stroke affects the opposite hemisphere. There is no certain way of predicting when the second embolus will strike. However, the occurrence of this second event, once thought to be as high as 20 percent, has been revised downward, to perhaps 2 percent, based on several large trials that were designed to test the effects of anticoagulation (see the review of Swanson). This has a bearing on the choice of early treatment after embolic stroke.

**Treatment and Prevention** Three phases of therapy—(1) general medical management in the acute phase, (2) measures directed to restoring the circulation, and (3) physical therapy and rehabilitation—are much the same as described earlier, under “Atherothrombotic Infarction.” Issues pertaining to the prevention of recurrent embolism are discussed below. Thrombolysis has been successful to the extent indicated previously, under “Thrombolytic Therapy” (page 694), and should be attempted by intravenous injection of t-PA when practical. There is no evidence that the risk of symptomatic hemorrhage (6 to 20 percent) from this treatment is any higher than in other types of stroke. Embolectomy at the bifurcation of the common carotid artery has usually failed; it is therefore rarely attempted. Similarly, embolectomy of the middle cerebral artery has been successful only in rare cases and is rarely undertaken. However, intra-arterial thrombolysis, by a catheter or thrombolytic agent, is being studied by several means, mainly as a method of restoring cerebral circulation in the period beyond the 3 h of opportunity for intravenous thrombolysis.

Of prime importance is the prevention of cerebral embolism; this applies both to patients who have had an episode of embolism and to those who have not but are at risk of doing so. The long-term use of anticoagulants has proved to be effective in the prevention of embolism in cases of atrial fibrillation, myocardial infarction, and valve prosthesis, as noted below. The roles of aspirin and warfarin depend on the specific circumstances and presumed origin of the embolus.

The most convincing evidence favoring the efficacy of anticoagulants in the prevention of embolism in one group of patients has been presented by the Boston Area Anticoagulant Trial for Atrial Fibrillation. The special group of patients at risk for stroke from chronic atrial fibrillation was maintained for 2 years on warfarin (INR of 1.5 to 2); there were 212 anticoagulated patients and 208 controls. Recurrent strokes were reduced by 86 percent in the warfarin group, and the death rate was also lower. One fatal hemorrhage occurred in each group; minor hemorrhages occurred in 38 of the warfarin group and in 21 of the control group. In a similar study from Copenhagen, the incidence of stroke in a group receiving warfarin was calculated to be 2 percent per year, in comparison to 5.5 percent per year in an untreated group. Several subsequent trials have attested to the efficacy of warfarin in the prevention of stroke in patients with nonrheumatic atrial fibrillation (Singer). Subsequent studies have suggested that an INR between 2 and 3
confers better protection than levels below 2. It should be pointed out, however, that patients below 65 years of age in these trials did not clearly benefit from long-term prophylactic anticoagulation unless there were additional risk factors such as diabetes, hypertension, congestive heart failure, or cardiac valvular disease. This group, called "lone fibrillators" which embodies a low risk for stroke, constitutes about one-third of adults with atrial fibrillation. Aspirin does not appear to afford the same degree of protective benefit in these circumstances, but some studies suggest a slightly better outcome than with no treatment; it has been used in younger patients and in those unable to take warfarin.

In patients with atrial fibrillation of recent onset, an attempt should be made to restore normal sinus rhythm by the use of electrical cardioversion or a trial of antiarrhythmic drugs. If these fail, prophylactic anticoagulant therapy is recommended. Before attempting cardioversion of more long-standing atrial fibrillation, anticoagulation for several days or longer is recommended.

With regard to aspirin treatment when the stroke is of unknown origin but presumed to be embolic, the data are uncertain. Most large trials comparing aspirin to warfarin have studied patients in whom cardiogenic embolus is not implicated (such as in the earlier mentioned WARSS study), but there are probably many cases that have a cardiac source nonetheless (see earlier discussion of treatment for thrombotic stroke).

There is no unanimity of opinion about the use and timing of anticoagulation with warfarin after an embolic stroke, in part because the risk of recurrent stroke in the first days is low (see comments on pages 696). On the basis of the aforementioned large trials of acute anticoagulation that show a 2 percent frequency of early recurrent stroke, many clinicians prefer to start warfarin and await its effects rather than using heparin. Nonetheless, once a firm diagnosis of embolic occlusion has been made, and particularly if there has been a recent myocardial infarction, a recent onset of atrial fibrillation, or a demonstrated cardiac thrombus on the echocardiogram, our customary practice has been to begin heparin on the same or the next day, generally without a loading dose, followed by the institution of warfarin on the same or the two following days. However, many of our colleagues no longer use heparin in this setting, and others even forgo the use of warfarin unless a definite source of embolism is detected by echocardiography. The recent trend has been to avoid heparin and simply start warfarin if it is indicated. Whether the newer low-molecular-weight heparins, mentioned earlier in the chapter, yield an advantage over conventional heparin treatment is not known. Patients with very large cerebral infarcts that have a component of deep (basal ganglionic) tissue damage and especially patients who are also hypertensive, there is a distinct risk of anticoagulant-related hemorrhage into the acute infarct (Shields et al). In these patients, anticoagulation therapy should perhaps be avoided in the acute setting.

Also in our opinion, the use of anticoagulant therapy is desirable for at least several weeks or months in most patients with acute myocardial infarction, especially if the left side of the heart is involved. In cerebral embolism associated with subacute bacterial endocarditis, anticoagulant therapy should be used cautiously because of the danger of intracranial bleeding, and one proceeds instead with antibiotics. We have generally not anticoagulated these patients.

Valvuloplasty, removal of verrucous lesions in endocarditis, and amputation of the atrial appendage have substantially reduced the incidence of embolism in the now infrequent rheumatic heart disease. The need for special care in preventing emboli that arise from the cardiac chambers or the aortic arch from entering the carotid arteries during the performance of valvuloplasty is appreciated by all cardiac surgeons.

**Generalized Brain Ischemia and Hypoxia** (See Chap. 40)

This constitutes a special group of infarctions that follow cardiac arrest and other forms of prolonged hypotension or hypoxia. In the case of reduced blood flow to the cerebral hemispheres, there is a tendency for focal infarctions to occur in the regions of lowest blood flow that lie between the major surface arteries, so-called watershed infarctions. In the extreme case, there is global infarction of the brain accompanied by the clinical syndrome of brain death. Pure hypoxia-anoxia produces another type of damage in areas susceptible to reduced oxygen delivery, mainly the hippocampi; here a Korsakoff syndrome results. Most often, ischemic and hypoxic states coexist and may produce complex patterns of cerebral damage. This topic is discussed fully in Chap. 40, “The Acquired Metabolic Diseases of the Nervous System.” The special problem of cerebral ischemia during cardiac surgery with the use of a bypass pump is discussed further on in the section on “Stroke with Cardiac Surgery.”

**LESS COMMON CAUSES OF OCCLUSIVE CEREBROVASCULAR DISEASE**

(See also pages 730 to 734)

**Fibromuscular Dysplasia**

This is a segmental, nonatheromatous, noninflammatory arterial disease of unknown etiology. It is uncommon (0.5 percent of 61,000 arteriograms in the series of So et al), but it is being reported with increasing frequency because of improved arteriographic techniques. In our experience, it has often been an incidental finding in asymptomatic individuals undergoing aortic angiography.

First described in the renal artery by Leadbetter and Burkland in 1938, fibromuscular dysplasia is now known to affect other vessels, including cervicocerebral ones. The internal carotid artery is involved most frequently, followed by the vertebral and cerebral arteries. The radiologic picture consists of a series of transverse constrictions, giving the appearance of an irregular string of beads or a tubular narrowing; it is observed bilaterally in 75 percent of cases. Usually only the extracranial part of the artery is involved. In the series of Houser and colleagues, 42 of 44 patients were women, and 75 percent were over 50 years of age. All of the patients reported by So and coworkers were women, ranging in age from 41 to 70 years. Cerebral ischemia may be associated with the process but the rate of this complication has not been established. Our impression is that it is low. Among 79 untreated asymptomatic patients followed for an average of 5 years, 3 had a cerebral infarct 4 to 18 years after the initial diagnosis in the study by Corrin et al. Also, between 7 and 20 percent of affected individuals are found to have intracranial saccular aneurysms (rarely a giant aneurysm), which may be a source of subarachnoid hemorrhage, and 12 percent develop arterial dissections, as described below.

The pathology of this disease has been summarized by Schievink and colleagues. The narrowed arterial segments show degeneration of elastic tissue and irregular arrays of fibrous and smooth muscle tissue in a mucous ground substance. Dilatations are due to atrophy of the coat of the vessel wall. There is atherosclerosis
in some and arterial dissection in others. Usually vascular occlusion is not present, though there may be marked stenosis. In some instances the mechanism of the cerebral ischemic lesion is unexplained. Possibly thrombi form in the pouches or in relation to intraluminal septa.

So and colleagues have recommended excision of the affected segments of the carotid artery if the neurologic symptoms are related to them and conservative therapy if the fibromuscular dysplasia is an incidental arteriographic finding in an asymptomatic patient. It is now possible to dilate the affected vessel by means of endovascular techniques, and several case reports have suggested that benefit is achieved at lower risk in this way than with surgical excision. Associated intracranial saccular aneurysms should be sought by arteriography or magnetic resonance angiography and surgically obliterated if their size warrants it (page 722). It is not known if anticoagulation or antiplatelet therapy confer protection from stroke.

Dissection of the Cervical and Intracranial Vessels

Internal Carotid Artery Dissection

It has long been appreciated that the process formerly known as Erdheim’s mediocereosis aortica cystica, the main cause of aortic dissection, may extend into the common carotid arteries, occluding them and causing massive infarction of the cerebral hemispheres. Examples of such an occurrence were cited by Weisman and Adams in 1944 in their study of the neurology of dissecting aneurysms of the aorta. In more recent years, attention has been drawn to the occurrence of spontaneous dissection of the internal carotid artery and the fact that it is an important cause of hemiplegia in young adults. Several large series of such cases have been reported in separate studies by Ojemann, Mokri, and Bogousslavsky and their colleagues.

Traumatic or apparently spontaneous carotid dissection is a not uncommon cause of stroke, particularly in younger individuals. Bogousslavsky and colleagues found 30 instances (comprising both genders) in 1200 consecutive patients with a first stroke (2.5 percent). It should be suspected in young adult women (typically in their late thirties or early forties), who seem especially susceptible to the condition, either as a spontaneous event or in relation to a whiplash injury, bouts of violent coughing, or direct trauma to the head or neck, which need not be severe—e.g., being struck in the neck by a golf or tennis ball. We have also encountered cases that occurred during pregnancy and immediately after delivery. Indeed, it is questionable if many cervical arterial dissections are truly “spontaneous,” since most can be connected to some strenuous event. Three of our patients over the years had a carotid dissection that was manifest as a hemiplegia days after blunt head injury. A small number of patients have fibromuscular disease, as discussed above; the Ehlers-Danlos and Marfan syndromes, osteogenesis imperfecta, and alpha-1-antitrypsin deficiency are also associated with an increased risk of vascular dissection. One of these conditions should be suspected if multiple extracranial vessels are involved in spontaneous dissections (neck and thoracic trauma are more common causes of this configuration).

It is of interest that a few patients with carotid dissection have had warning attacks of unilateral cranial or facial pain, followed, within minutes to days, by signs of ischemia in the territory of the internal carotid artery. The pain is nonthrobbing and centered most often in and around the eye; less often, it is in the frontal or temporal regions, angle of the mandible, or high anterior neck over the carotid artery. Rapid and marked relief of the pain after the administration of corticosteroids is virtually a diagnostic feature (see below). The ischemic manifestations consist of transient attacks in the territory of the internal carotid, followed frequently by the signs of hemispheral stroke, which may evolve smoothly over a period of a few minutes to hours or over several days in a fluctuating or stepwise fashion. A unilateral Horner syndrome is often present. Cervical bruit—sometimes audible to the patient, amaurosis fugax, faintness and syncope, and facial numbness are less common symptoms. Most of the patients described by Mokri and coworkers presented with one of two distinct syndromes: (1) unilateral headache associated with an ipsilateral Horner syndrome or (2) unilateral headache and delayed focal cerebral ischemic symptoms. Some patients have evidence of involvement of the vagus, spinal accessory, or hypoglossal nerve; these nerves lie in close proximity to the carotid artery and are nourished by small branches from it.

In most cases, dissection of the internal carotid artery can be detected by ultrasound and confirmed by MRI, which shows a double lumen, and by MRA. These procedures may obviate the need for arteriography. The latter procedure reveals an elongated, irregular, narrow column of dye, usually beginning 1.5 to 3 cm above the carotid bifurcation and extending to the base of the skull, a picture that Fisher has called the string sign. There may be a tapered occlusion or an outpouching at the upper end of the string. Less often the dissection is confined to the midcervical region, and occasionally it extends into the middle cerebral artery or involves the opposite carotid artery or the vertebral and basilar arteries.

The extensive study by Mokri and colleagues showed that a complete or excellent recovery occurred in 85 percent of patients with the angiographic signs of dissection; mainly, these were patients without stroke. The outcome in cases complicated by stroke is far less benign. About one-quarter of such patients succumb and one-half of the survivors remain seriously impaired (Bogousslavsky et al). In the remainder, early recanalization of the occluded artery can be observed (as determined by ultrasonography), with good functional recovery. Pseudoaneurysms form in a small proportion of patients and generally do not require surgical repair; they also do not preclude cautious anticoagulation.

The pathogenesis of spontaneous carotid dissection is at present uncertain. In most of the recently reported cases, cystic medial necrosis has not been found on microscopic examination of the involved artery. In some, there was a disorganization of the media and internal elastic lamina, but the specificity of these changes is in doubt, since Ojemann and colleagues noted similar changes in some of their control cases. In a small proportion of cases there are the changes of fibromuscular dysplasia, as noted earlier. A more thorough study of these vessels in routine autopsy material is needed.

Treatment The treatment has usually been immediate anticoagulation to prevent embolism—using first heparin, then warfarin—but it must be acknowledged that this approach has not been demonstrated to be more successful than careful observation. Once a stroke has occurred, even though embolic in most cases, prompt reopening of the artery can at times prove beneficial; this is currently performed by endovascular techniques. Despite numerous publications demonstrating the ability of skilled operators to reopen a dissection by endovascular methods, acute intervention has not been studied in a way that allows a judgment regarding its value. Whether stent placement is additionally beneficial has also not been
Treatment
dissection of multiple extracranial vessels; this also occurs as a
found that some patients have evidence of spontaneous or traumatic
ultrasound investigation documents the same. Mokri et al have
sequences, show a double lumen in the dissected vessel, and skillful
the relationship. Axial MRI images, particularly the T1-weighted
inciting event by several days or weeks or even longer, obscuring
neck, head trauma, or Valsalva straining or coughing activities—
such as chiropractic manipulation of the
persistent occipitonuchal pain is prominent and follows one of the
infarction of the cervical spinal cord, presumably from occlusion
quite unlike the usual vertebrobasilar TIA.

Vertebral Artery Dissection Dissection of these arteries is less
common than dissection of the extracranial carotid artery but is
being recognized with increasing frequency. It may originate in
the neck and extend into the intracranial portion of the vessel or remain
isolated to either of these segments. In both instances there is a
tendency to form pseudoaneurysms, but this is more likely with the
intracranial type, and only in the latter is there a risk of rupture
through the adventitia, leading to a subarachnoid hemorrhage.
Rapid and extreme rotational movement of the neck is the most
common identifiable cause, as in turning the head to back up a car.
Chiropractic manipulation has been one precipitant. Extending the
neck to have one’s hair washed, and swinging a golf club have also
led to dissection. Forceful coughing may also cause dissection, as
in the carotid vessels. There is no female predominance (in contrast
to carotid dissection), but the previously cited intrinsic weaknesses
of the vascular wall from Ehlers-Danlos disease and fibromuscular
dysplasia are risk factors.

The dissection usually originates in the C1-C2 segment of the
vessel, where it is mobile but tethered as it leaves the transverse
foramen of the axis and turns sharply to enter the cranium. The
symptoms, mainly vertigo, derive from the lateral medullary syn-
drome, often with additional features referable to the pons or mid-
brain, particularly diplopia and dysarthria. The clinical manifesta-
tions in our experience have fluctuated over minutes and hours,
quite unlike the usual vertebrobasilar TIA.

Less common strokes include artery-to-artery embolism to the
posterior cerebral territory or, a syndrome that has come to our
attention several times in the past few years, a centrally placed
infarction of the cervical spinal cord, presumably from occlusion
of the anterior spinal artery.

The diagnosis of vertebral dissection should be suspected if
persistent occipitocervical pain is prominent and follows one of the
known precipitants—such as chiropractic manipulation of the
neck, head trauma, or Valsalva straining or coughing activities—
but it may otherwise escape detection until the full-blown medul-
ary or cerebellar stroke is established. The latter may follow the
inciting event by several days or weeks or even longer, obscuring
the relationship. Axial MRI images, particularly the T1-weighted
sequences, show a double lumen in the dissected vessel, and skillful
ultrasound investigation documents the same. Mokri et al have
found that some patients have evidence of spontaneous or traumatic
dissection of multiple extracranial vessels; this also occurs as a
consequence of dissection of the aortic arch from chest trauma.

Treatment This has usually been with heparin anticoagulation
followed for a period by warfarin, but the precise duration of treat-
ment is difficult to determine and the same uncertainties as to ef-
effectiveness of anticoagulation and of stent placement discussed
above in regard to carotid dissection pertain here. Whether there is
an inordinate risk of subarachnoid hemorrhage with intracranial
dissection has not been settled. The usual practice is to repeat an
imaging or ultrasound study several months after the dissection and
discontinue the anticoagulation if the vessel lumen has been re-
established sufficiently to allow good blood flow. Pseudoaneu-
rysms in the cervical portions of the vessels generally do not require
specific treatment.

As with other dissections, corticosteroids may relieve the ini-
tial associated pain.

Intracranial Arterial Dissection Dissections of intracranial ar-
teries are less common than extracranial dissections and present in
several ways. A number of times we have misinterpreted the ar-
teriographic appearance of a short segment of narrowing of the
basilar or proximal middle cerebral arteries, assuming these
changes to represent embolism or arteritis when in fact they proved
to be dissections of the vessel wall. In the case of purely intracranial
dissection of the middle cerebral or basilar arteries, there is usually
no preceding trauma, but a few patients have had minor head in-
juries, extreme coughing, or other Valsalva-producing events (e.g.,
after childbirth)—or they had used cocaine. The typical picture is
of fluctuating symptoms referable to the affected circulation and
severe cranial pain on the side of the occlusion—retro-orbital in
the case of middle cerebral dissection, occipital in the case of basi-
lar dissection, occipital combined with supraorbital in the case of
vertebral dissection (see above). A few have had sudden strokes
that suggested embolic infarction, and a small number present with
subarachnoid hemorrhage.

Treatment This is primarily with anticoagulation and follow-up
angiography. It is notable that corticosteroids have relieved the
cranial and retro-orbital pain in our cases, and dramatic relief of
pain within an hour is a virtually diagnostic. Endovascular revas-
cularization has been attempted with mixed results, the main prob-
lem being catastrophic and usually fatal vessel rupture during an-
gioplasty.

Moyamoya Disease

*Moyamoya* is a Japanese word for a “cloud of smoke” or “haze”; it has been used in recent years to refer to an *extensive basal cerebr al rete mirabile*—a network of small anastomotic vessels at the base of the brain around and distal to the circle of Willis, seen in carotid arteriograms, along with segmental stenosis or occlusion of the terminal parts of both internal carotid arteries.

Nishimoto and Takeuchi have reported on 111 cases that were
selected on the basis of these two radiologic criteria. The condition
was observed mainly in infants, children, and adolescents (more
than half the patients were less than 10 years of age, and only 4 of
the 111 were above age 40). All of the patients were Japanese; both
males and females were affected, and 8 were siblings. The symp-
tom that led to medical examination was usually a sudden weakness
of an arm, leg, or both on one side. The weakness tended to clear
rapidly but recurred in some instances. Headache, convulsions, im-
paired mental clarity, visual disturbance, and nystagmus occurred
less frequently. In older patients, subarachnoid hemorrhage was the
most common initial manifestation. Other symptoms and signs
were speech disturbance, sensory impairment, involuntary move-
ments, and unsteady gait. Only 6 of the entire series became worse
after the initial illness, and 4 died. Characteristics noted by others
include prolonged TIAs (this accords with our experience), charac-
teristically induced by hyperventilation or hyperthermia, paren-
chymal rather than subarachnoid hemorrhages (most are situated
in the basal ganglia or thalamus), and an unusual “rebuildup” EEG
phenomenon in which high-voltage slow waves reappear 5 min
after the end of hyperventilation.

Postmortem examination of these cases has yielded a reason-
ably clear picture of the distal carotid lesion. The adventitia, media, and internal elastic laminae of the stenotic or occluded arteries were normal, but the intima was greatly thickened by fibrous tissue. No inflammatory cells or atheromata were seen. In a few cases, hypoplasia of the vessel with absent muscularis has been described. The rete mirabile consists of a fine network of vessels over the basal surface (in the pia-arachnoid), which, according to Yamashita and coworkers, reveal microaneurysm formation due to weakness of the internal elastic lamina and thinness of the vessel wall. The latter lesion is the source of subarachnoid hemorrhage. Thus one part of the symptomatology is traced to the distal carotid stenosis and another to the rupture of the vascular network.

This form of cerebrovascular disease is not limited to the Japanese. The authors have periodically observed such patients, as have others, in the United States, western Europe, and Australia. Opinion is divided as to whether the basal rete mirabile represents a congenital vascular malformation (i.e., a persistence of the embryonal network) or a rich collateral vascularization secondary to a congenital hypoplasia, acquired stenosis, or occlusion of the internal carotid arteries early in life. The association between moyamoya, Down syndrome, and certain HLA types favors a hereditary basis (Kitahara et al).

**Treatment**
The treatment of moyamoya is far from satisfactory. Certain surgical measures have been employed, including transplantation of a vascular muscle flap, omentum, or pedicle containing the superficial temporal artery to the pial surface of the frontal lobe, with the idea of creating neovascularization of the cortical convexity. These measures have reportedly reduced the number of ischemic attacks, but whether they alter the natural history of the illness cannot be stated. Anticoagulation has been considered risky in view of the possibility of cerebral hemorrhage, but there are no systematic studies.

**Binswanger Disease**

Binswanger disease has been mentioned briefly in the discussion of the course and prognosis of atherothrombotic infarction and as a cause of dementia in Chaps. 21 and 39. The term has come to denote a widespread degeneration of cerebral white matter having a vascular causation and observed in the context of hypertension, atherosclerosis of the small blood vessels, and multiple strokes (see page 909). Hemiparesis, dysarthria, TIAs, and typical lacunar or cortical strokes are admitted in many cases. The process has been associated with a particular radiologic appearance that reflects the confluence of areas of white matter changes. The term leukoareosis, meant to describe the less intense appearance of periventricular tissues in imaging studies, complicates the matter, since this condition is also assumed to have a vascular basis, and the term has been used indiscriminately, particularly by some radiologists, as equivalent to Binswanger disease. Whether multiple discrete lacunes in the deep white matter constitutes Binswanger disease may be a semantic issue, but we adhere to the notion that the former is characterized by a more confluent and widespread ischemic and gliotic change in the deep white matter.

Dementia, a pseudobulbar state, and a gait disorder, alone or in combination, are the main features of Binswanger cases. They have been attributed to the cumulative effects of the ischemic changes and specifically to the white matter degeneration. The pathologic basis of such a clinical entity has not been well delineated. More importantly, the gliosis that is found in white matter has been assumed to represent a special type of ischemic change, but the vessels in these regions have never been adequately studied (by serial sections). Yet another problem, as mentioned, is to distinguish such a state from deficits produced by the cumulative effect of numerous larger lacunes, which have for a century been known to cause the aforementioned syndromes of dementia, gait disturbance, and a pseudobulbar syndrome. From time to time, imaging studies of the brain disclose large regions of white matter change or the occurrence of multiple infarctions in the absence of hypertension, and it is not clear how such cases should be classified. Some prove to be areas of demyelination or metabolic dysmyelination, others are mitochondrial disorders, and perhaps some are related to the familial syndrome discussed below. Fabry disease also enters into the differential diagnosis of multiple small infarctions in the cerebral that may coalesce into areas of white matter damage (page 839). Readers should consult the reviews by Babikian and Ropper, by Caplan, and by Mohr and Mast.

**Familial Subcortical Infarction (CADASIL)**

A process similar to Binswanger leukoencephalopathy, but without hypertension, has been identified as an autosomal dominant familial trait linked in several families to a mutation on chromosome 19. It had been described previously under a number of names, including hereditary multi-infarct dementia. The acronym CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is now applied. In these patients, recurrent small strokes, often beginning in early adulthood, culminate in a subcortical dementia. Migraine headaches, often with neurologic accompaniments, may precede the strokes by several years, as may numerous and varied TIAs that are attributed, probably incorrectly, to the migraine. Some individuals display few clinical changes; others are demented or have strokes that simulate lacunes. We are unable to comment on the encephalopathy and coma, in some cases accompanied by fever, described by Schon and colleagues. It seems to represent another very rare condition.

The familial nature of the process may not be appreciated because genetic penetrance is not complete until after 60 years of age. On MRI scans, clinically unaffected family members may show substantial changes in the white matter well before strokes or dementia arises. In some cases, particularly in Japan, early alopecia and lumbar spondylisis have been associated with CADASIL.

The MRI and CT appearance of multiple confluent white matter lesions of various sizes, many quite small and concentrated around the basal ganglia and periventricular areas, is similar to that in Binswanger disease. When these are asymmetrical and periventricular, they are difficult to distinguish from the lesions of multiple sclerosis. In the autopsy cases studied by Jung and colleagues, numerous partially cavitated infarctions were found in the white matter and basal ganglia. In the regions of these infarctions were small vessels, 100 to 200 mm diameter, in which the media contained basophilic granular deposits with degeneration of the smooth muscle fibers. Attribution of the white matter degeneration to these vascular changes presents the same problems as in Binswanger disease, particularly in view of patency of most of the many small vessels in the material. Again, the relation of the vascular changes to lesions in the brain has not been studied in serial sections. Nevertheless, CADASIL is probably the main cause of sporadic instances of what otherwise passes for Binswanger disease but without the obligate hypertension of the latter. Also, migraine headaches are not a component of Binswanger disease.
The responsible mutation on chromosome 19 of the Notch 3 gene, in the same locus as the gene for familial hemiplegic migraine, has been characterized by Joutel and colleagues; this provides a diagnostic test that can be performed on the blood or skin. However, the mechanism by which this leads to the vasculopathy or white matter changes is not clear. The diagnosis can also be confirmed by finding eosinophilic inclusions in the arterioles of a skin biopsy (osmophlic with electron microscopy). Awareness of this apparently vascular form of white matter degeneration adds to the list of inherited leukoencephalopathies, the others being inherited metabolic disturbances, as discussed in Chap. 38.

**Amyloid Angiopathy**

This process is discussed further on in relation to lobar cerebral hemorrhages in the elderly. The angiopathy consists of the deposition of amyloid in the media and adventitia of small vessels, predominantly in the meninges, cortex, and cortical penetrating vessels. The incidence at autopsy of vascular amyloid deposition in the brain is related to the age of the population studied; rates of 12 percent are cited in patients above 85 years of age (the same changes are present in over 25 percent of individuals with Alzheimer disease, but the nature of the amyloid is different in the two conditions). Over the last few years, however, our colleague Greenberg has emphasized certain clinical features associated solely with cerebrovascular amyloidosis. Of interest here are multiple TIAs, some with migrainous features such as spreading sensory symptoms, and fairly rapid progression to dementia. Telltale signs of small hemorrhages that are more characteristic of diffuse cerebrovascular amyloid are often present in these cases. These old hemorrhages are seen to advantage with gradient echo sequences on the MRI. The frequency of this interesting condition in the elderly is unclear. There is a separate familial amyloidotic condition of diffuse white matter degeneration with dementia, associated in some families with calcification in the occipital lobes.

**Strokes in Children and Young Adults**

As indicated in Table 34-2, it is probable that ischemic necrosis of cerebral tissue can occur in utero. The resulting stroke is usually referred to as congenital hemiplegia. However, very little is known about the underlying vascular lesions, so that nothing further can be said about them here.

The occurrence of acute hemiplegia in infants and children is a well-recognized phenomenon. In a series of 555 consecutive postmortem examinations at the Children’s Medical Center in Boston, there were 48 cases (8.7 percent) of occlusive vascular disease of the brain (Banker). The occlusions were both embolic (mainly associated with congenital heart disease) and thrombotic, and the latter were actually more common in veins than in arteries. Similarly, stroke is not an uncommon event in young adults (15 to 45 years). This group accounts for an estimated 3 percent of cerebral infarctions. In terms of causation, this group is remarkably heterogeneous. In a series of 144 such patients, more than 40 possible etiologies were identified (H. P. Adams et al). Nevertheless, 78 percent of the group could be accounted for by three categories, more or less equal in size: atherosclerotic thrombotic infarction (usually with a recognized risk factor); cardiogenic embolism (particularly in association with rheumatic heart disease, bacterial and verrucous endocarditis, paradoxic embolism through patent foramen ovale, and prosthetic valves); and nonatherosclerotic vasculopathies (arterial trauma, dissection of the carotid artery, moyamoya, lupus erythematosus, drug-induced, vasculitis). Hematologically related disorders—use of oral contraceptives (see further on), the postpartum state, and hypercoagulable states—were the probable causes in 15 percent of the 144 patients. The presence of antiphospholipid or anticardiolipin antibodies (lupus anticoagulant) appears to explain some of these cases and is discussed further under “Stroke as a Complication of Hematologic Disease”; the majority of these patients are women in their thirties without manifest systemic lupus erythematosus.

Despite the attention they have received as a cause of strokes in the juvenile period, the frequency of thrombophilic disorders due to inherited deficiencies of naturally occurring anticoagulant factors is low. The main inherited prothrombotic clotting defects are summarized in Table 34-8. They predispose primarily to cerebral venous cloting. Most arise from partial protein deficiencies due to heterozygous mutations in the genes encoding proteins that are important factors in the clotting cascade (antithrombin III, proteins S and C) and those due to disturbances of clotting balance (resistance to activated protein C, or factor V Leiden mutation, and prothrombin mutations as well as excess factor VIII) (see discussion by Brown and Bevan). However, when they are homozygous, these mutations may be associated with devastating neonatal hemorrhagic conditions. In some series that report cases of strokes in youth, such that of Becker and colleagues, up to half of the cases had one of these disorders, the commonest being the factor V Leiden mutation, but others have found this mutation to be much less frequent, and that is consonant with our experience. Nevertheless, in children with unexplained stroke, particularly venous and especially if there has been a previous thrombosis or if the strokes are recurrent, it is advisable to carry out an extensive hematologic investigation, especially including testing for antiphospholipid antibody (an acquired defect), as described on page 735. Establishing a diagnosis of a prothrombotic clotting gene variant has therapeutic significance, since strokes are prone to occur in the setting of such additional risks as the use of oral contraceptives or smoking. In adults, the evaluation for inherited clotting defects is far less fruitful. Furthermore, it should be kept in mind that the levels of proteins C and S and of antithrombin are temporarily depressed after stroke, so that any detected abnormalities must be confirmed months later.

Persistent cerebral ischemia and infarction may occasionally complicate migraine in young persons. The combination of migraine and “the Pill” is particularly hazardous, as detailed below. Similarly, despite the common occurrence of mitral valve prolapse in young adults, it is probably only rarely a cause of stroke (see comments on page 710). Stroke due to either arterial or venous occlusion occurs occasionally in association with ulcerative colitis and to a lesser extent with regional enteritis. Evidence points to a hypercoagulable state during exacerbations of inflammatory bowel disease, but a precise defect in coagulation has not been identified. Meningovascular syphilis and fungal and tuberculous meningitis and other forms of chronic basal meningitis are considerations in this age group; the strokes are usually of the cavitory lacunar type, resulting from infectious-inflammatory occlusion of small basal vessels.

Sickle cell anemia is a rare but important cause of stroke in children of African ancestry; acute hemiplegia is the most common manifestation, but all types of focal cerebral disorders have been observed. The pathologic findings are those of infarction, large and small; their basis is assumed to be vascular obstruction associated with the sickling process. Intracranial bleeding (subdural, subarach-

**Key:** AD, autosomal dominant; AR, autosomal recessive; v, venous; a, arterial; ao, aorta; h, heart.

Nond, and intracerebral) and cerebral venous thrombosis may also complicate sickle cell anemia, and—perhaps because of autosplenectomy—there is an increased incidence of pneumococcal meningitis. Treatment of the cerebral circulatory disorder, based presumably on sludging of red blood cells, is with intravenous hydration and transfusion. Cerebral venous sinus thrombosis in young children and neonates represents a special problem, difficult to diagnose, and with a poor prognosis (see de Veber et al).

Certain hereditary metabolic diseases (*homocystinuria* and *Fabry angiokeratosis*) and the mitochondrial disorder *MELAS* (mitochondrial encephalomyopathy, lactic acidosis, and stroke), discussed on page 839, may give rise to strokes in children or young adults; investigation of these causes is undertaken if the aforementioned diagnoses have been excluded.

Overall, in children and young adults with ischemic stroke, the main diagnoses to be considered are carotid and vertebral dissection, drug abuse (mainly cocaine), thrombosis induced by birth control pills (see below), antiphospholipid antibody syndrome, and patent foramen ovale (PFO). Migraine might be added to this list, but it is a diagnosis by exclusion in these circumstances and CADASIL, albeit rare, should also be considered if migraine headaches and TIAs precede a stroke. Inherited prothrombotic states—such as those caused by the various clotting factor deficiencies discussed above, Fabry disease, moyamoya, and Takayasu arteritis—arise in the younger age group and require exploration if clinical circumstances suggest on the basis of unusual TIAs (orthostatic or hyperventilation induced), Down syndrome, or strong family history of strokes in youth.
Oral Contraceptives, Estrogen, and Cerebral Infarction  The early studies of Longstreth and Swanson and of Vessey et al clearly indicated that women who take oral contraceptives in the child-bearing years—particularly if they are older than 35 years of age and also smoke, are hypertensive, or have migraine—are at increased risk of cerebral infarction as well as of ischemic heart disease and subarachnoid hemorrhage. Cerebral infarction in these cases is due to arterial occlusion, occurring in both the carotid-middle cerebral and vertebrobasilar territories. In most of the reported fatal cases, the thrombosed artery has been free of atheroma or other disease. This has been taken to indicate that embolism is responsible for the strokes, but the source of embolism can rarely be demonstrated. Cerebral and noncerebral venous thromboses are other relatively rare complications. These observations, coupled with evidence that estrogen alters the coagulability of the blood, suggest that a state of hypercoagulability is an important factor in the genesis of contraceptive-associated infarction.

The vascular lesion underlying cerebral thrombosis in women taking oral contraceptives has been studied by Irey and colleagues. It consists of nodular intimal hyperplasia of eccentric distribution with increased acid mucopolysaccharides and replication of the internal elastic lamina. Similar changes have been found in pregnancy and in humans and animals receiving exogenous steroids, including estrogens. Whether these promote in situ thrombosis is not known. Mainly at increased risk of stroke are women taking high-dose (0.50-mg) estrogen pills; lowering the estrogen content does not reduce the incidence. Mainly at increased risk of cerebral infarction as well as of ischemic heart disease and subarachnoid hemorrhage. Cerebral infarction in these cases is due to arterial occlusion, occurring in both the carotid-middle cerebral and vertebrobasilar territories. In most of the reported fatal cases, the thrombosed artery has been free of atheroma or other disease. This has been taken to indicate that embolism is responsible for the strokes, but the source of embolism can rarely be demonstrated. Cerebral and noncerebral venous thromboses are other relatively rare complications. These observations, coupled with evidence that estrogen alters the coagulability of the blood, suggest that a state of hypercoagulability is an important factor in the genesis of contraceptive-associated infarction.

These observations, coupled with evidence that estrogen alters the coagulability of the blood, suggest that a state of hypercoagulability is an important factor in the genesis of contraceptive-associated infarction.

Stroke with Cardiac Surgery  Incident to cardiac arrest and bypass surgery there is risk of both generalized and focal hypoxia-ischemia of the brain. Improved operative techniques have lessened the incidence of these complications, but they are still distressingly frequent. Fortunately, most of these cerebral disorders are transient. Atherosclerotic plaques may be dislodged during cross-clamping of the proximal aorta and are an important source of cerebral emboli. In the last decade the incidence of stroke related to cardiac surgery has dropped to between 2 and 3 percent in large series numbering thousands of patients (Libman et al, Algren and Aren). Advanced age, congestive heart failure, and more complex surgeries have been listed as risk factors for stroke in various reports. In a retrospective study by Dashe and colleagues, 2.2 percent had strokes, and the risk was greatly increased (greater than 70 percent) on the side of a carotid stenosis. Curiously, almost one-fifth of postoperative strokes have been of lacunar type. In one prospective study of 2108 patients who underwent coronary operations in several institutions, 3 percent had strokes or TIAs and the same number had a deterioration of cognitive function; mostly the adverse effects occurred in older patients and were transient (Roach et al).

Mohr and coworkers examined 100 consecutive cases pre- and postoperatively and observed two types of complications—one occurring immediately after the operation and the other after an interval of days or weeks. The immediate neurologic disorder consisted of a delay in awakening from the anesthesia; subsequently there was slowness in thinking, disorientation, agitation, combative, visual hallucinations, and poor registration and recall of what was happening. These symptoms, in the form of a confusional state sometimes verging on delirium or acute psychosis, usually cleared within 5 to 7 days, although some patients were not entirely normal mentally some weeks later. As the confusion cleared, about half of the patients were found to have small visual field defects, dyscalculia, oculomotor ataxia, alexia, or defects of perception suggestive of lesions in the parieto-occipital regions. The immediate effects were attributed to hypotension and various types of embolism (atherosclerotic, air, silicon, fat, platelets). The delayed effects were more clearly embolic and were especially frequent in patients having prosthetic valve replacements. However, they also occurred subsequent to arterial homografts.

In addition to overt and covert strokes, a degree of cognitive decline and depression is to be expected in a proportion of patients undergoing coronary artery bypass grafting. The frequency of these changes is reported to be between 40 and 70 percent (see page 363). It is our impression that many of these neurologic complications, both small strokes and cognitive abnormalities, pass unnoticed in many cardiac surgical units. This was emphasized in the study by McKhann and colleagues, who extensively tested several neuropsychologic areas and found that only 12 percent of patients escaped some type of early cognitive problem. However, several other studies, such as the one by Mülges and colleagues, have suggested that only a small proportion (13 percent in their series) have permanent effects 5 years after operation. Others have reported...
higher rates, but it is clear that the cognitive problems improve over time in the majority of patients.

The use of Doppler insonation of the middle cerebral arteries is being studied to detect transient signals called HITs (high-intensity transients) as a manifestation of small emboli during surgery—but, as in cerebral arteriography, the clinical importance of these emboli is not known.

The special stroke problems related to prosthetic heart valves—mainly infective endocarditis causing embolic strokes and anticoagulant-related cerebral hemorrhage—are described in appropriate sections of this chapter.

**INTRACRANIAL HEMORRHAGE**

This is the third most frequent cause of stroke. Although more than a dozen causes of nontraumatic intracranial hemorrhage are listed in Table 34-9, primary or hypertensive (“spontaneous”) intracerebral hemorrhage, ruptured saccular aneurysm and vascular malformation, and hemorrhage associated with the use of anticoagulants or thrombolytic agents account for the majority. Cerebrovascular amyloidosis and bleeding disorders account for a small number. The small brainstem hemorrhages secondary to temporal lobe herniation and brainstem compression (Duret hemorrhages), hypertensive encephalopathy, and brain purpura might be included in this group, but they do not simulate a stroke.

**Primary (Hypertensive) Intracerebral Hemorrhage**

This is the mundane “spontaneous” brain hemorrhage. It is due predominantly to chronic hypertension and degenerative changes in cerebral arteries. In recent decades, with increased awareness of the need to control blood pressure, the proportion of hemorrhages attributable to causes other than hypertension has greatly increased; more than half such hemorrhages on our services now occur in normotensive individuals, and the hemorrhages more often than previously arise in locations that are not typical for hypertension. Nevertheless, the hypertensive cerebral hemorrhage serves as a paradigm for understanding and managing the cerebral hemorrhage.

In order of frequency, the most common sites of a cerebral hemorrhage are (1) the putamen and adjacent internal capsule (50 percent); (2) the central white matter of the temporal, parietal, or frontal lobes (lobar hemorrhages, not strictly associated with hypertension); (3) the thalamus; (4) a cerebellar hemisphere; and (5) the pons (see Weisberg et al). The vessel involved is usually a penetrating artery that originates from a larger trunk vessel. About 2 percent of primary hemorrhages are multiple. Rarely the bleeding is solely intraventricular, possibly from the choroid plexus. The problem is one of bleeding that occurs within brain tissue; rupture of arteries lying in the subarachnoid space is practically unknown apart from aneurysms and some vascular malformations.

The extravasation of blood forms a roughly circular or oval mass that disrupts the tissue and grows in volume as the bleeding continues (Fig. 34-20). Adjacent brain tissue is distorted and compressed. If the hemorrhage is large, midline structures are displaced to the opposite side and reticular activating and respiratory centers can be compromised, leading to coma and death in the manner described in Chap. 17. Both the size and the location of the clot determine the degree of upper brainstem compression (Andrew et al). Rupture or seepage into the ventricular system may occur, and the CSF becomes bloody in these cases. However, a hemorrhage of this type almost never ruptures through the cerebral cortex. When the hemorrhage is small and located at a distance from the ventricles, the CSF may remain clear even on repeated examina-

*Figure 34-20. An unenhanced CT scan showing the typical picture of a massive primary (hypertensive) hemorrhage in the basal ganglia. The third ventricle and ipsilateral lateral ventricle are compressed and displaced by the expanding mass (12 h after onset of stroke).*
tion. In the first hours and days following the hemorrhage, a limited amount of edema accumulates around the clot and adds to the mass effect. Hydrocephalus may occur as a result of bleeding into the ventricular system or from compression of the third ventricle.

Extravasated blood undergoes a predictable series of changes. At first fluid, it clots within hours. Before the clot forms, red cells may settle in the dependent part of the hematoma and form a meniscus with the plasma above; this is particularly prone to occur in cases of anticoagulant-induced hemorrhage. A fluid-fluid level is then observed on scans (“hematocrit effect”). Only masses of red blood cells (RBCs) and proteins are found within the hematoma; rarely one sees a few remnants of destroyed brain tissue. The hematoma is surrounded by petechial hemorrhages from torn arterioles and venules. Within a few days, hemoglobin products, mainly hemosiderin and hematoxycin, begin to appear. The hemosiderin forms within histiocytes that have phagocytized RBCs and takes the form of ferritin granules, which stain positively for iron. As oxyhemoglobin is liberated from the RBCs and becomes deoxygenated, methemoglobin is formed. This begins within a few days and imparts a brownish hue to the periphery of the clot. Phagocytosis of RBCs begins within 24 hours, and hemosiderin is first observed around the margins of the clot in 5 to 6 days. The clot changes color gradually, over a few weeks, from dark red to pale red, and the border of golden-brown hemosiderin widens. The edema disappears over many days or weeks. In 2 to 3 months, larger clots are filled with a chromo-colored mesh, which is slowly absorbed, leaving a smooth-walled cavity (slit hemorrhage) or a yellow-brown scar. The iron pigment (hematin) becomes dispersed and studs adjacent astrocytes and neurons. It may persist well beyond the border of the hemorrhage for years.

In CT scans, fresh blood is visualized as a white mass as soon as it is shed. The mass effect and the surrounding extruded serum and edema are hypodense. After 2 to 3 weeks, the surrounding edema begins to recede and the density of the hematoma decreases, first at the periphery. Gradually the clot becomes isodense with brain. There may be a ring of enhancement from the hemosiderin-filled macrophages and the reacting cells forming the capsule of the hemorrhage. By MRI, either in conventional T1- or T2-weighted images, the hemorrhage is not easily visible in the 2 or 3 days after bleeding, since oxyhemoglobin is diamagnetic or, at most, is slightly hypointense, so that only the mass effect is evident. After several days the surrounding edema is hyperintense in T2-weighted images. As deoxyhemoglobin and methemoglobin form, the hematoma signal becomes bright on T1-weighted images and dark on T2. As the hematoma becomes subacute, the dark images gradually brighten. When methemoglobin disappears and only hemosiderin remains, the entire remaining mass is hypodense on T2-weighted images, as are the surrounding deposits of iron. MR images that display areas of magnetic susceptibility will show hemorrhages earlier and detect remnants of deposited hemosiderin even years afterwards.

Hemorrhages may be described as massive, moderate, small, slit, and petechial. Massive refers to hemorrhages several centimeters in diameter; small applies to those 1 to 2 cm in diameter and less than 20 mL in volume; a moderate-sized hemorrhage, of course, falls between these two, both in diameter and in volume. Slit refers to an old collapsed hypertensive or traumatic hemorrhage that lies just beneath the cortex.

Pathogenesis The hypertensive vascular lesion that leads to arterial rupture in some cases appears to arise from an arterial wall altered by the effects of hypertension, i.e., the change referred to in a preceding section as segmental lipohyalinosis and the false aneurysm (microaneurysm) of Charcot-Bouchard. Ross Russell has affirmed the relationship of these microaneurysms to hypertension and hypertensive hemorrhage and their frequent localization on penetrating small arteries and arterioles of the basal ganglia, thalamus, pons, and subcortical white matter. However, in the few hemorrhages examined in serial sections by our colleague C. M. Fisher, the bleeding could not be traced to Charcot-Bouchard aneurysms. Takebayashi and coworkers, in an electron microscopic study, found breaks in the elastic lamina at multiple sites, almost always at bifurcations of the small vessels. Possibly these represent sites of secondary rupture from tearing of small vessels by the expanding hematoma.

Clinical Picture Of all the cerebrovascular diseases, brain hemorrhage is the most dramatic and from ancient times has been surrounded by “an aura of mystery and inevitability.” It has been given its own name, “apoplexy.” The prototype is an obese, plethoric, hypertensive male who, while sane and sound, falls senseless to the ground—impervious to shouts, shaking, and pinching—breathes stertorously, and dies in a few hours. A massive blood clot escapes from the brain as it is removed postmortem. With smaller hemorrhages, the clinical picture conforms more closely to the usual temporal profile of a stroke, i.e., an abrupt onset of symptoms that evolve gradually and steadily over minutes or hours, depending on the size of the ruptured artery and the speed of bleeding.

Several general features of intracerebral hemorrhage should be emphasized. Acute reactive hypertension, far exceeding the patient’s chronic hypertensive level, is a feature that should always suggest hemorrhage; it is seen with moderate and large clots situated in deep regions. Vomiting at the onset of intracerebral hemorrhage occurs much more frequently than with infarction and should always suggest bleeding as the cause of an acute hemiparesis. Severe headache is generally considered to be an accompaniment of intracerebral hemorrhage and in many cases it is, but in almost 50 percent of our cases headache has been absent or mild in degree. Nuchal rigidity is found frequently; but again, it is so often absent or mild that failure to find it should not eliminate the diagnosis. (Stiffness of the neck characteristically disappears as coma deepens). It should also be noted that the patient is often alert and responding accurately when first seen. This can be true even when the CSF is grossly bloody; thus the adage that hemorrhage into the ventricular system always precipitates coma is quite incorrect. Only if bleeding into the ventricles is massive will coma result. Seizures, usually focal, occur in the first few days in some 10 percent of cases of supratentorial hemorrhage, rarely at the time of the ictus but more commonly as a delayed event, months or even years after the hemorrhage, in association with subcortical slit hemorrhages. The fundi often show hypertensive changes in the arterioles. Rarely, white-centered retinal hemorrhages (Roth spots) or fresh preretal (subhyaloid) hemorrhages occur; the latter are much more common with ruptured aneurysm, arteriovenous malformation, or severe trauma. Headache, acute hypertension, and vomiting with a focal neurologic deficit are therefore the cardinal features and serve most dependably to distinguish hemorrhage from ischemic stroke.

Very small hemorrhages in “silent” regions of the brain may escape clinical detection. Hemorrhages that complicate the administration of anticoagulants, like those from some vascular malformations, may evolve at a slower pace. Usually there are no warn-
main types of cerebral hemorrhage are described below.

**Putaminal Hemorrhage**  The most common syndrome is the one due to putaminal hemorrhage, with extension to the adjacent internal capsule (Fig. 34-20). The neurologic symptoms and signs vary slightly with the precise site and size of the extravasation, but hemiplegia from interruption of the capsule is a consistent feature of medium-sized and large clots. Vomiting occurs in about half the patients. Headache is frequent but not invariable. With large hemorrhages, patients lapse almost immediately into a stupor with hemiplegia, and their condition visibly deteriorates as the hours pass. More often, however, the patient complains of headache or of some other abnormal cephalic sensation. Within a few minutes the face sags on one side, speech becomes slurred or aphasic, the arm and leg gradually weaken, and the eyes tend to deviate away from the side of the paretic limbs. These events, occurring gradually over a period of a few minutes to a half hour, are strongly suggestive of intracerebral bleeding. The paralysis may worsen; a Babinski sign appears, at first unilaterally and then bilaterally; the affected limbs become flaccid; painful stimuli are not appreciated; speaking becomes impossible; and confusion gives way to stupor. The most advanced stages are characterized by signs of upper brainstem compression (coma); bilateral Babinski signs; deep, irregular, or intermittent respiration; dilated, fixed pupils, first on the side of the clot; and occasionally by decerebrate rigidity.

The widespread use of CT scanning has disclosed the frequent occurrence of smaller putaminal hemorrhages, which in former times would have been misdiagnosed as embolic or thrombotic ischemic strokes (especially if the CSF was clear). With hemorrhages confined to the anterior segment of the putamen, the hemiplegia and hyperreflexia tend to be less severe and to clear more rapidly (Caplan). There is also prominent abulia, motor impairment, temporary unilateral neglect, and—with left-sided lesions—nonfluent aphasia and dysgraphia. With posterior lesions, weakness is also less and is attended by sensory loss, hemianopia, impaired visual pursuit to the opposite side, Wernicke-type aphasia (left-sided lesions), and anosognosia (right-sided).

Caplan has also analyzed the effects of relatively pure caudate hematomata. Those extending laterally and posteriorly into the internal capsule behave much like large putaminal hemorrhages. Those extending medially into the lateral ventricle give rise to drowsiness, stupor, and either confusion and underactivity or restlessness and agitation.

**Thalamic Hemorrhage**  The central feature here is severe sensory loss on the entire contralateral body. If large or moderate in size, thalamic hemorrhage also produces a hemiplegia or hemiparesis by compression or destruction of the adjacent internal capsule (Fig. 34-21). The sensory deficit is usually severe and involves all of the opposite side, including the trunk, and may exceed the motor weakness. A fluent aphasia may be present with lesions of the dominant side, and amorphosynthesis and contralateral neglect with lesions of the nondominant side. A homonymous field defect, if present, usually clears in a few days.

Thalamic hemorrhage, by virtue of its extension into the sub-
thalamus and high midbrain, may cause a series of ocular disturbances—pseudo-abducens palsies with one or both eyes turned asymmetrically inward and slightly downward, palsies of vertical and lateral gaze, forced deviation of the eyes downward, inequality of pupils with absence of light reaction, skew deviation with the eye ipsilateral to the hemorrhage assuming a higher position than the contralateral eye, ipsilateral ptosis and miosis (Horner syndrome), absence of convergence, retraction nystagmus, and tucking in (retraction) of the upper eyelids. Extension of the neck may be observed. Compression of the adjacent third ventricle leads to enlargement of the lateral ventricles, and this requires temporary drainage of the ventricles in a small proportion of patients. Small and moderate-sized hemorrhages that rupture into the third ventricle are seemingly associated with fewer neurologic deficits and better outcomes, but early hydrocephalus is almost invariable.

**Pontine Hemorrhage** Here deep coma usually ensues in a few minutes, and the clinical picture is dominated by total paralysis, decerebrate rigidity, and small (1-mm) pupils that react to light. Lateral eye movements, evoked by head turning or caloric testing, are impaired or absent. Death usually occurs within a few hours, but there are rare exceptions in which consciousness is retained and the clinical manifestations indicate a smaller lesion in the tegmentum of the pons (disturbances of lateral ocular movements, crossed sensory or motor disturbances, small pupils, and cranial nerve palsies) in addition to signs of bilateral corticospinal tract involvement. A small number of our patients with small tegmental hemorrhages and blood in the CSF have survived, with good functional recovery. In a series of 60 patients with pontine hemorrhage reviewed by Nakajima, 19 survived (8 of these had remained alert). Similarly, Wijdicks and St. Louis reported that 21 percent made a good recovery—mostly those who were alert on admission.

**Cerebellar Hemorrhage** This usually develops over a period of one to several hours, and loss of consciousness at the onset is unusual. Repeated vomiting is a prominent feature, along with occipital headache, vertigo, and inability to sit, stand, or walk. Often these are the only abnormalities, making it imperative to have the patient attempt to stand and walk; otherwise the examination may be falsely normal. In the early phase of the illness, other clinical signs of cerebellar disease may be minimal or lacking; only a minority of cases show nystagmus or cerebellar ataxia of the limbs, although these signs must always be sought. A mild ipsilateral facial weakness and a diminished corneal reflex are common. Dysarthria and dysphagia may be prominent in some cases but usually are absent. Contralateral hemiplegia and ipsilateral facial weakness do not occur unless there is displacement and compression of the medulla against the clivus. There is often paresis of conjugate lateral gaze to the side of the hemorrhage, forced deviation of the eyes to the opposite side, or an ipsilateral sixth nerve weakness. Vertical eye movements are retained. Other ocular signs include blepharospasm, involuntary closure of one eye, skew deviation, “ocular bobbing,” and small, often unequal pupils that continue to react until very late in the illness.

Occasionally, at the onset, there is a spastic paraparesis or a quadriaparesis with preservation of consciousness. The plantar reflexes are flexor in the early stages but extensor later. When these signs occur, hydrocephalus is present and may require drainage. In the series of St. Louis et al, those with vermian clots and hydrocephalus were at the highest risk for deterioration. As the hours pass, and occasionally with unanticipated suddenness, the patient becomes stuporous and then comatose or suddenly apneic as a result of brainstem compression, at which point reversal of the syndrome, even by surgical therapy, is seldom successful.

**Lobar Hemorrhage** Bleeding in areas other than those listed above, specifically in the subcortical white matter of one of the lobes of hemisphere, is not associated strictly with hypertension; it is presented here for ease of exposition. Any number of other causes are usually responsible, the main ones being anticoagulation or thrombolytic therapy, arteriovenous malformation (discussed further on), trauma, and, in the elderly, amyloidosis of the cerebral vessels.

In a series of 26 cases of lobar hemorrhage, we found 11 to lie within the occipital lobe (with pain around the ipsilateral eye and a dense homonymous hemianopia); 7 in the temporal lobe (with pain in or anterior to the ear, partial hemianopia, and fluent aphasia); 4 in the frontal lobe (with frontal headache and contralateral hemiplegia, mainly of the arm); and 3 in the parietal lobe (with anterior temporal headache and hemisensory deficit contralaterally) (Ropper and Davis). The smaller hematomas simulate an embolic stroke in the same territory. The occurrence of a progressively worsening headache, vomiting, and drowsiness in conjunction with any one of these syndromes is virtually diagnostic, and, of course, a lobar hemorrhage is readily corroborated by an unenhanced CT scan. Of our 26 patients, 14 had normal blood pressure, and in several of the fatal cases there was amyloidosis of the affected vessels (see further on). Also, 2 patients were receiving anticoagulants, 2 had an arteriovenous malformation, and 1 had a metastatic tumor. In a series of 22 patients with lobar clots reported by Kase and colleagues, 55 percent were normotensive; metastatic tumors, arteriovenous malformations, and blood dyscrasias were found in 14, 9, and 5 percent of the patients, respectively. The role of amyloid angiopathy in lobar hemorrhage in the elderly patient is discussed further on.

In the localization of an intracerebral hemorrhage, ocular signs are particularly important. In putaminal hemorrhage, the eyes are deviated to the side opposite the paralysis; in thalamic hemorrhage, the commonest ocular abnormality is downward deviation of the eyes and the pupils may be unreactive; in pontine hemorrhage, the eyeballs are fixed and the pupils are tiny but reactive; in large cerebellar hemorrhage, the eyes are deviated laterally to the side opposite the lesion and ocular bobbing may occur.

Although the proper interpretation of this array of clinical data allows the correct diagnosis to be established in most cases, the ancillary examinations described below are definitive, especially in the diagnosis of small hemorrhages.

**Laboratory Findings** Among laboratory methods for the diagnosis of intracerebral hemorrhage, the CT scan occupies the foremost position. This procedure has proved totally reliable in the detection of hemorrhages that are 1.0 cm or more in diameter. Smaller pontine hemorrhages are visualized with less certainty. At the same time, coexisting hydrocephalus, tumor, cerebral swelling, and displacement of the intracranial contents are readily appreciated. MRI is particularly useful for demonstrating brainstem hemorrhages and residual hemorrhages, which remain visible long after they can no longer be seen by the CT scan (after 4 to 5 weeks). Hemosiderin and iron pigment have their own characteristic appearances, as described earlier.

In general, lumbar puncture is ill advised, for it may precipitate or aggravate an impending shift of central structures and herniation. The white cell count in the peripheral blood may rise tran-
siently to 15,000/mm³, a higher figure than in thrombosis. The sedimentation rate is mildly elevated in some patients.

Course and Prognosis The immediate prognosis for large and medium-sized cerebral clots is grave; some 30 to 35 percent of patients die in 1 to 30 days. Either the hemorrhage extends into the ventricular system or intracranial pressure is elevated to levels that preclude normal perfusion of the brain. Sometimes the hemorrhage itself seeps into vital centers such as the hypothalamus or midbrain. A formula that predicts outcome of hemorrhage based on clot size has been devised by Broderick and coworkers; it is mainly applicable to putaminal and thalamic hemorrhages. They found a close correlation with outcome. A volume of 30 mL or less, calculated from the CT scan, predicted a generally favorable outcome; only 1 of their 71 patients with clots larger than 30 mL had regained independent function by 1 month. By contrast, in patients with clots of 60 mL or larger and an initial Glasgow Coma Scale score of 8 or less, the mortality was 90 percent (this scale is detailed on page 754). As remarked earlier, it is the location of the hematoma, not simply its size, that determines the clinical effects. A clot 60 mL in volume is almost uniformly fatal if situated in the basal ganglia but may be more benign if located in the frontal or occipital lobe. From the studies of Diringer and colleagues, it appears that hydrocephalus is also an important predictor of poor outcome, and this accords with our experience.

In patients who survive—i.e., in those with smaller hemorrhages—there can be a surprising degree of restoration of function, since, in contrast to infarction, the hemorrhage has to some extent pushed brain tissue aside rather than destroyed it. Function may return very slowly, however, because extravasated blood takes time to be removed from the tissues. Also, since rebleeding from the same site is unlikely, the patient may live for many years. In some instances of medium-sized cerebral and cerebellar hemorrhages, papilledema appears after several days of increased intracranial pressure. This does not mean that the hemorrhage is increasing in size or swelling—only that papilledema is slow to develop. Healed scars impinging on the cortex are liable to be epileptogenic; the frequency of seizures after each type of hemorrhage has not been established, but it is lower than for ischemic strokes. There is probably no need to administer anticonvulsive medication unless a seizure has occurred.

The poor prognosis of all but the smallest pontine hemorrhages has already been mentioned. Cerebellar hemorrhages present special problems that are discussed below.

Treatment The management of patients with large intracerebral hemorrhages and coma includes the maintenance of adequate ventilation, use of controlled hyperventilation to a PCO₂ of 25 to 30 mmHg, monitoring of intracranial pressure in some cases and its control by the use of tissue-dehydrating agents such as mannitol (osmolality kept at 295 to 305 mosmol/L and Na at 145 to 150 meq), and limiting intravenous infusions to normal saline. Qureshi’s group has offered data suggesting that aggressive measures to reduce intracranial pressure may be lifesaving and result in good outcome even in patients who have signs of transtentorial herniation. In our experience, this type of recovery is exceptional, but treatment may be justified in some patients whose medical condition allows it.

As mentioned, virtually all patients with intracerebral hemorrhage are hypertensive immediately after the stroke because of a generalized sympathoadrenal response. The natural trend is for the blood pressure to diminish over several days; therefore active treatment in the acute stages has been a matter of controversy. Rapid reduction in blood pressure, in the hope of reducing further bleeding, is not recommended, since it risks compromising cerebral perfusion in cases of raised intracranial pressure. On the other hand, sustained mean blood pressures of greater than 110 mmHg may exaggerate cerebral edema and risk extension of the clot. It is at approximately this level of acute hypertension that the use of beta-blocking drugs (esmolol, labetalol) or angiotensin-converting enzyme (ACE) inhibitors is recommended. The major calcium channel blocking drugs are used less often for this purpose because of reports of adverse effects on intracranial pressure, although this information derives mainly from patients with brain tumors. Hayashi and associates have shown that blood pressure is lowered with nifedipine after cerebral hemorrhage, but intracranial pressure is raised, resulting in an unfavorable net reduction in cerebral perfusion pressure. We have, nevertheless, used this class of medication in patients with small and medium-sized clots without adverse effects. Diuretics are helpful in combination with any of the antihypertensive medications. More rapidly acting and titratable agents such as nitroprusside may be used in extreme situations, recognizing that they may further raise intracranial pressure.

Surgical evacuation of a hemispheral clot in the acute stage may occasionally be lifesaving, and we have referred numerous patients for surgical treatment when hemispheral hemorrhages were larger than 3 cm in diameter and the clinical state was deteriorating. The most successful surgical results have been in patients with lobar or moderate-sized putaminal hemorrhages. Although selected patients may be saved from progression to brain death, the focal neurologic deficit is not altered. Even this modest result requires that operation be carried out before or very soon after coma supervenes. But, on the basis of numerous small studies, it must be stated that surgical results have generally not been superior to those with medical measures alone (Waga and Yamamoto, Batjer et al, Juvela et al; Rabinstein et al). It would appear intuitively that the removal of an acutely formed clot from the cerebral hemispheres should be greatly beneficial, but it has been difficult to demonstrate this effect in various groups of patients. Once the patient becomes deeply comatose with dilated fixed pupils, the chance of any recovery is negligible. In part, disappointing results have been the result of combining patients in various stages of stupor and coma, undoubtedly with different levels of intracranial pressure and clots of various sizes and locations. Even in organized (if retrospective) studies in which clinical worsening was the reason for surgery, such as the one by Rabinstein and colleagues, only one-quarter of patients attained a state of functional independence. All of their patients who lost their brainstem reflexes and had extensor posturing died despite surgery; there are few exceptions to this observation.

In comatose patients with large hemorrhages, we have found that the placement of a device for constant monitoring of intracranial pressure enables the clinician to use medical measures with greater precision, as outlined in Chap. 17, but there is no evidence that outcome is significantly improved (Ropper and King). Whether hemicraniectomy is of value, as it is with large hemispheral strokes, is not known.

In contrast, the surgical evacuation of cerebellar hematomas is a generally accepted treatment and is a more urgent matter because of the proximity of the mass to the brainstem and the risk of abrupt progression to coma and respiratory failure. Also, hydrocephalus from compression of the fourth ventricle more often complicates the clinical picture and further raises intracranial pressure.
As a rule, a cerebellar hematoma of less than 2 cm in diameter leaves most patients awake and infrequently leads to deterioration, therefore not requiring surgery. Hematomas that are 4 cm or more in largest diameter, especially if located in the vermis, pose the greatest risk, and some surgeons have recommended evacuation of lesions of this size no matter what the clinical status of the patient. In determining the need for surgical evacuation, we have been guided by the state of consciousness, the mass effect caused by the clot as visualized on CT scan (particularly the degree of compression of the quadrigeminal cistern, as pointed out by Taneda and colleagues), and the presence of hydrocephalus. Often this requires daily or even more frequent CT scans. The patient who is stuporous or displays arhythmic breathing is best intubated and brought to the operating room within hours or sooner. Once coma and pupillary changes supervene, few patients survive, even with surgery; however, rapid medical intervention with mannitol and hyperventilation, followed by surgical evacuation of the clot and drainage of the ventricles very soon after the onset of coma, has been successful in a few cases. Patients who are only drowsy and those with hematomas of 2 to 4 cm in diameter pose the greatest difficulty in deciding about surgery. If the level of consciousness is fluctuating or if there is obliteration of the perimesencephalic cisterns, particularly if coupled with hydrocephalus, we believe that the risk of surgery is less than that of a sudden deterioration. In only a very limited number of patients have we found it practical to perform only drainage of the enlarged ventricles, although some groups still favor this procedure and eschew a posterior fossa operation. In our experience, evacuation of the clot has been more important than reduction of hydrocephalus.

**Spontaneous Subarachnoid Hemorrhage (Ruptured Saccular Aneurysm)**

This is the fourth most frequent cerebrovascular disorder—following atherothrombosis, embolism, and primary intracerebral hemorrhage, but one that is often disastrous. Saccular aneurysms are also called “berry” aneurysms; actually they take the form of small, thin-walled blisters protruding from arteries of the circle of Willis or its major branches. Their rupture causes a flooding of the subarachnoid space with blood under high pressure. As a rule, the aneurysms are located at vessels bifurcations and branchings (Fig. 34-22) and are generally presumed to result from developmental defects in the media and elastica. An alternate theory holds that the aneurysmal process is initiated by focal destruction of the internal elastic membrane, which is produced by hemodynamic forces at the apices of bifurcations (Ferguson). As a result of the local weakness, the intima bulges outward, covered only by adventitia; the sac gradually enlarges and may finally rupture. Saccular aneurysms vary in size from 2 mm to 2 or 3 cm in diameter, averaging 7.5 mm (Wiebers et al). Those that rupture usually have a diameter of 10 mm or more (by angiography), but rupture also occurs, albeit less often, in those of smaller size. Aneurysms vary greatly in form. Some are round and connected to the parent artery by a narrow stalk, others are broad-based without a stalk, and still others take the form of narrow cylinders. The site of rupture is usually at the dome of the aneurysm, which may have one or more secondary sacculations. A review of the subject by Schievink is recommended for further details.

In routine autopsies, the incidence of unruptured aneurysms is almost 2 percent—excluding minor outpouchings of 3 mm or less. Aneurysms are multiple in 20 percent of patients. It has been estimated that 400,000 Americans harbor unruptured aneurysms and that there are an estimated 26,000 subarachnoid hemorrhages from them per year (Sahs et al). In childhood, rupture of saccular aneurysms is rare, and they are seldom found at routine postmortem examination; beyond childhood, they gradually increase in frequency to reach their peak incidence between 35 and 65 years (average 49 years). Therefore they cannot be regarded as fully formed congenital anomalies; rather, they appear to develop over the years on the basis of either a developmental or acquired arterial defect.

**Figure 34-22.** Diagram of the circle of Willis showing the principal sites of saccular aneurysms. Approximately 90 percent of aneurysms are on the anterior half of the circle. The sizes of the aneurysms depicted correspond roughly to the frequency of occurrence at those sites.
There is an increased incidence of congenital polycystic kidneys, fibromuscular dysplasia of the extracranial arteries, moyamoya, and coarctation of the aorta among persons with saccular aneurysms. A saccular aneurysm occurs in approximately 5 percent of cases of arteriovenous malformation, usually on the main feeding artery of the malformation.

Numerous reports have documented a familial occurrence of saccular aneurysms, lending support to the idea that genetic factors play a role in their development. The number of first-degree relatives found to harbor an unsuspected aneurysm has been about 4 percent in most series. This low rate, the finding that half of the discovered aneurysms are small, and the complications of surgery make routine screening of siblings, children, and parents of patients with ruptured aneurysms impractical, according to the Magnetic Resonance Angiography in Relatives of Patients with Subarachnoid Hemorrhage Study Group. However, since aneurysms of the familial variety tend to be larger at the time of rupture and more numerous than in patients who have sporadic ones, there are exceptions to this statement (Ruigrok et al).

While hypertension is more frequently present than in the general population, nevertheless aneurysms most often occur in persons with normal blood pressure. Pregnancy does not appear to be associated with an increased incidence of aneurysmal rupture, although there is always concern about the possibility of rupture during the straining of natural delivery. Atherosclerosis, though present in the walls of some saccular aneurysms, probably plays no part in their formation or enlargement.

Approximately 90 to 95 percent of saccular aneurysms lie on the anterior part of the circle of Willis (Fig. 34-22). The four most common sites are (1) the proximal portions of the anterior communicating artery, (2) at the origin of the posterior communicating artery from the stem of the internal carotid, (3) at the first major bifurcation of the middle cerebral artery, and (4) at the bifurcation of the internal carotid into middle and anterior cerebral arteries. Other sites include the internal carotid artery in the cavernous sinus, at the origin of the ophthalmic artery, the junction of the posterior communicating and posterior cerebral arteries, the bifurcation of the basilar artery, and the origins of the three cerebellar arteries. Aneurysms that rupture in the cavernous sinus may give rise to an arteriovenous fistula (page 749).

There are several types of aneurysm other than saccular, e.g., mycotic, fusiform, diffuse, and globular. The mycotic aneurysm is caused by a septic embolus that weakens the wall of the vessel in which it lodges (page 727). The others are named for their predominant morphologic characteristics and consist of enlargement or dilatation of the entire circumference of the involved vessels, usually the internal carotid, vertebral, or basilar arteries. The latter are also referred to as arteriosclerotic aneurysms, since they frequently show atheromatous deposition in their walls, but it is likely that they are at least partly developmental in nature. Some are gigantic and press on neighboring structures or become occluded by thrombus; they rupture only infrequently (see further on).

Clinical Syndrome With rupture of the aneurysm, blood under high pressure is forced into the subarachnoid space (usually in relation to the circle of Willis), and the resulting clinical events assume one of three patterns: (1) the patient is stricken with an excruciating generalized headache and vomiting and falls unconscious almost immediately; (2) headache develops in the same manner but the patient remains relatively lucid—the most common syndrome; (3) rarely, consciousness is lost quickly without any preceding complaint. Decerebrate rigidity and brief clonic jerking of the limbs may occur at the onset of the hemorrhage, in association with unconsciousness. If the hemorrhage is massive, death may ensue in a matter of minutes or hours, so that ruptured aneurysm must be considered in the differential diagnosis of sudden death. A considerable proportion of such patients probably never reach a hospital. Persistent deep coma is accompanied by irregular respirations, attacks of extensor rigidity, and finally respiratory arrest and circulatory collapse. In these rapidly fatal cases, the subarachnoid blood has greatly increased the intracranial pressure to a level that approaches arterial pressure and caused a marked reduction in cerebral perfusion. In some instances the hemorrhage has dissected intracerebrally and entered the ventricular system.

Rupture of the aneurysm usually occurs while the patient is active rather than during sleep, and in a few instances during sexual intercourse, straining at stool, lifting heavy objects, or other sustained exertion (see page 160). Momentary Valsalva maneuvers, as in coughing or sneezing, have generally not caused aneurysmal rupture (they may cause arterial dissection). In patients who survive the initial rupture, the most feared complication is rerupture, an event that may occur at any time from minutes up to 2 or 3 weeks.

In less severe cases, consciousness, if lost, may be regained within a few minutes or hours, but a residuum of drowsiness, confusion, and amnesia accompanied by severe headache and stiff neck persists for several days. It is not uncommon for the drowsiness and confusion to last 10 days or longer. Since the hemorrhage is confined to the subarachnoid space, there are few if any focal neurologic signs. That is to say, gross lateralizing signs in the form of hemiplegia, hemiparesis, homonymous hemianopia, or aphasia are absent in the majority of cases. On occasion, a jet of blood emanating from an aneurysm may rupture into the adjacent brain or clot in the insular cistern and produce a hemiparesis or other focal syndrome. There may also be a focal syndrome from acute or delayed ischemia in the territory of the aneurysm-bearing artery. Usually this occurs several days after a large subarachnoid hemorrhage. The pathogenesis of such manifestations is not fully understood, but a transitory fall in pressure in the circulation distal to the aneurysm is postulated in early cases and vasospasm is responsible for the later focal signs. Transient deficits are not common, but they do constitute reliable indicators of the site of the ruptured aneurysm (see below).

Convulsive seizures, usually brief and generalized, occur in 10 to 25 percent of cases according to Hart et al (but far less often in our experience) in relation to acute bleeding or rebleeding. These early seizures do not correlate with the location of the aneurysm and do not appear to alter the prognosis.

Prior to rupture, saccular aneurysms are usually asymptomatic. Exceptionally, if large enough to compress pain-sensitive structures, they may cause localized cranial pain. With a cavernous or anterolaterally situated aneurysm on the first part of the middle cerebral artery, the pain may be projected to the orbit. An aneurysm on the posteroirterior or anteroinferior cerebellar artery may cause unilateral occipital or cervical pain. The presence of a partial oculomotor palsy with dilated pupil may be indicative of an aneurysm of the posterior communicating—internal carotid junction (less often posterior communicating—posterior cerebral junction). Occasionally, large aneurysms just anterior to the cavernous sinus may compress the optic nerves or chiasm, third nerve, hypothalamus, or pituitary gland. In the cavernous sinus they may compress the third, fourth, or sixth nerve or the ophthalmic division of the fifth nerve. A monoclonal visual field defect may also develop with a
suprACLINOID aneurysm near the anterior and middle cerebral bifurcation or the ophthalmic-carotid bifurcation.

Whether a small leak of blood from an aneurysm may serve as a warning sign of rupture ("warning leak") has been disputed. We have seen several cases where an acute and severe exertional or spontaneous headache was found to be associated with a small subarachnoid hemorrhage that was discovered by lumbar puncture; more often the headache is unrelated to hemorrhage and is attributable to migraine. This latter "thunderclap headache," which may be a variant of migraine, is discussed on page 160. A headache similar to that caused by subarachnoid hemorrhage may also be the reflection of pituitary apoplexy, cerebral venous thrombosis, hypertensive encephalopathy, intracranial hypotension, intracranial arterial dissection, and a condition characterized by diffuse cerebral vasospasm. This last entity may be spontaneous or due to the ingestion of sympathomimetic or serotoninergic drugs (see further on, under "Diffuse and Focal Cerebral Vasospasm."). The details of the CSF examination assume great importance in the diagnosis of subarachnoid hemorrhage and the exclusion of the disorders mentioned above.

Vasospasm Delayed hemiplegia and other focal deficits usually appear 3 to 12 days after rupture and rarely before or after this period. These delayed syndromes and the focal narrowing of a large artery or arteriovenous malformation and, rarely, hemorrhage into a cerebral artery. Areas of ischemic infarction in the territory of the vessel bearing the aneurysm, without thrombosis or other changes in the vessel, is the usual finding in such cases. These ischemic lesions are often multiple and occur with great frequency, according to Hijdra and associates (in 57 of 176 cases. These ischemic lesions are often multiple and occur with great frequency, according to Hijdra and associates (in 57 of 176 cases. These ischemic lesions are often multiple and occur with great frequency, according to Hijdra and associates (in 57 of 176
days following the bleed, but preceding hypertension is only slightly more common than in the general population. Levels of 200 mmHg systolic are seen occasionally just after rupture, but usually the pressure is elevated only moderately and fluctuates with the degree of head pain. Spontaneous intracranial bleeding with normal blood pressure should also suggest ruptured aneurysm or arteriovenous malformation and, rarely, hemorrhage into a cerebral tumor. Nuchal rigidity is usually present but occasionally absent, and the main complaint of pain may be referable to the intercapsular region or even the low back rather than to the head. Examination of the fundi frequently reveals smooth-surfaced, sharply
outlined collections of blood that cover the retinal vessels—the so-called preretinal or subhyaloid hemorrhages; Roth spots are seen occasionally. Bilateral Babinski signs are found in the first few days following rupture if there is hydrocephalus. Fever up to 39°C (102.2°F) may be seen in the first week, but most patients are afebrile. Rarely, escaping blood enters the subdural space and produces a hematoma, evacuation of which may be lifesaving.

Laboratory Findings A CT scan will detect blood locally or diffusely in the subarachnoid spaces or within the brain or ventricular system in more than 90 percent of cases and in practically all cases in which the hemorrhage has been severe enough to cause momentary or persistent loss of consciousness (Fig. 34-23). This should therefore be the initial investigative procedure. The blood may appear as a subtle shadow along the tentorium or in the Sylvian or adjacent fissures. A large localized collection of subarachnoid blood or a hematoma in brain tissue or within the Sylvian fissure indicates the adjacent location of the aneurysm and the likely region of subsequent vasospasm, as already noted. When two or more aneurysms are visualized by arteriography, the CT scan may identify the one that had ruptured by the clot that surrounds it. Also, coexistent hydrocephalus will be demonstrable. If the CT scan documents subarachnoid blood with certainty, a spinal tap is not necessary. MRI can also detect blood in the proton density sequence; after a day has passed, this can also be done with the fluid attenuated inversion recovery (FLAIR) technique.

In all other cases, where subarachnoid hemorrhage is suspected but not apparent on imaging studies, a lumbar puncture should be undertaken. Usually the CSF becomes grossly bloody within 30 min of the hemorrhage, with RBC counts up to 1 million/mm³ or even higher. With a relatively mild hemorrhage, there may be only a few thousand cells, but it is unlikely that a severe headache syndrome from subarachnoid hemorrhage would be associated with fewer than a several hundred cells. It is also probably not possible for an aneurysm to rupture entirely into brain tissue without some leakage of blood into the subarachnoid fluid. In other words, the diagnosis of ruptured saccular aneurysm (by lumbar puncture) is essentially excluded if blood is not present in the CSF. Xanthochromia is found after centrifugation if several hours or more have elapsed from the moment of the ictus. In a patient who reports a headache that is consistent with subarachnoid hemorrhage but the occurrence was several days earlier, the CT scan may be normal and xanthochromia the only diagnostic finding. To determine whether xanthochromia is present, fresh CSF must be centrifuged in a tube with a conical bottom and the supernatant compared to clear water in good light. It has been our experience that most hospital laboratories cannot be depended on to give accurate results for this test. Also helpful after several days is the MRI taken with the FLAIR sequence, which will demonstrate blood (the proton density sequence is more sensitive to blood in the first day).

The problem of a “traumatic tap” often clouds the early diagnosis and several aids to detecting this misleading laboratory result are discussed in Chap. 2. Here it is reiterated that in addition to the absence of xanthochromia, the most important are the clearing of blood as one continues to collect fluid and a marked reduction in the number of RBCs in serial tubes of spinal fluid. A normal opening pressure suggests puncture of a local vessel rather than a ruptured aneurysm. The combination of subarachnoid hemorrhage and a traumatic tap generally requires that vascular imaging procedures be performed to resolve the issue. The CSF in the first days

Figure 34-23. Subarachnoid hemorrhage due to rupture of a basilar artery aneurysm. Left: Axial CT scan image at the level of the lateral ventricles showing widespread blood in the subarachnoid spaces and layering within the ventricles with resultant hydrocephalus. There is a blood-CSF level in the posterior horns of the lateral ventricles, typical of recent bleeding. Right: At the level of the basal cisterns, blood can be seen surrounding the brainstem, in the anterior Sylvian fissures and the anterior interhemispheric fissure. The temporal horns of the lateral ventricles are again enlarged, reflecting acute hydrocephalus.
is under increased pressure, as high as 500 mmH$_2$O—an important finding in differentiating spontaneous subarachnoid hemorrhage from a traumatic tap. The proportion of WBCs to RBCs in the CSF is usually the same as in the circulating blood (approximately 1:700), but in some patients a brisk CSF leukocytosis appears within 48 h, sometimes reaching more than 1000 cells per cubic millimeter. The protein is slightly or moderately elevated and in some instances glucose is mildly reduced.

Carotid and vertebral angiography is the only certain means of demonstrating an aneurysm and does so in over 90 percent of patients in whom the correct diagnosis of spontaneous subarachnoid hemorrhage is made on clinical grounds. MRI with modern scanners (Fig. 34-24) detects most aneurysms of the basal vessels and of their first branches but may not yet be of sufficient sensitivity to replace conventional angiography in cases where an aneurysm is strongly suspected but too small to be detected by MRA. Even when MRA demonstrates the aneurysm, the surgeon usually requires the kind of anatomic definition that can be obtained only by conventional angiography. The most up-to-date CT technology scanning with contrast infusion has certainly begun to equal the detail provided by conventional angiography and has additional advantages of showing the lesion in relation to the adjacent brain and skull in multiple views. (Fig. 34-24)

Associated Systemic Changes Acute subarachnoid hemorrhage is associated with several characteristic responses in the systemic circulation, water balance, and cardiac function. The ECG changes include symmetrically large peaked T waves and other alterations suggesting subendocardial or myocardial ischemia. Also there is a tendency to develop hyponatremia; this abnormality and its relationship to intravascular volume depletion plays a key role in treatment, as discussed further on. Albuminuria and glycosuria may be present for a few days. Rarely, diabetes insipidus occurs in the acute stages, but water retention or a natriuresis is more frequent. There may be a leukocytosis of 15,000 to 18,000 cells per cubic millimeter, but the sedimentation rate is usually normal.

Course and Prognosis The outstanding characteristic of this condition, mentioned earlier, is the tendency for the hemorrhage to recur from the same site. This threat colors all prognostications and dominates modern treatment strategies. Unfortunately there appears to be no way of determining reliably which patients will bleed again. The cause of recurrent bleeding is not understood but may be related to naturally occurring mechanisms of clot formation and lysis at the site of initial rupture, usually at the dome of the aneurysm.

Patients with the typical clinical picture of spontaneous subarachnoid hemorrhage in whom an aneurysm or arteriovenous malformation cannot be demonstrated angiographically have a distinctly better prognosis than those in whom the lesion is visualized (Nishioka et al). In a series of 323 angiographically negative cases followed for an average of 10 years, there was rebleeding in only 12 (Hawkins et al). After 22 years, 69 percent of these patients had survived. It is customary in most centers to repeat the arteriogram in several weeks, because it has been observed that vascular spasm may have earlier obscured the aneurysm. It is advantageous to obtain x-rays from several different angles in order to expose those views that were obscured by adjacent overlying vessels. If the first study involves all cerebral vessels and utilizes several views of the basal circulation, it has been our experience that the second arteriogram is infrequently more revealing but our practice is to repeat it nonetheless.

Another clinical circumstance with a favorable outcome is limited perimesencephalic hemorrhage, described by van Gijn and colleagues. The cisterns surrounding the midbrain and upper pons are symmetrically filled with blood, the headache is mild, and signs of vasospasm do not develop. No aneurysm is found at the expected site for blood in this region, i.e., at the top of the basilar artery. The patient usually does well and a second arteriogram is probably not required. It has been speculated that the bleeding has a venous rather than an aneurysmal source.

As regards prognosis of aneurysmal hemorrhage, McKissock and colleagues decades ago found that the patient’s state of consciousness at the time of arteriography was the single best index of outcome, and this remains true today. Their data, representative of the status of aneurysm management in the 1950s and consonant with the natural history before the advent of modern surgical and intensive care techniques, indicated that of every 100 patients reaching a hospital and coming to arteriography, 17 were stuporous or comatose and 83 appeared to be recovering from the ictus. At

the end of the following 6 months, 8 of every 100 patients had died of the original hemorrhage and 59 had had a recurrence (with 40 deaths), making a total of 48 deaths and 52 survivors. In regard to recurrence of bleeding, it was found that of 50 patients seen on the first day of the illness, 5 rebled in the first week (all fatal), 8 in the second week (5 fatal), 6 in the third and fourth weeks (4 fatal), and 2 in the next 4 weeks (2 fatal), making a total of 21 recurrences (16 fatal) in 8 weeks.

The most comprehensive long-term analysis of the natural history of the disease is contained in the report of the Cooperative Study of Intracranial Aneurysms and Subarachnoid Hemorrhage (Sahs et al). This study was based on long-term observations of 568 patients who sustained an aneurysmal bleed between 1958 and 1965 and were managed only by a conservative medical program. A follow-up search in 1981 and 1982 disclosed that 378, or two-thirds of the patients, had died; 40 percent of the deaths had occurred within 6 months of the original hemorrhage. For the patients who survived the original hemorrhage for 6 months, the chances of survival during the next two decades were significantly worse than those of a matched normal population. Rebleeding occurred at a rate of 2.2 percent per year during the first decade and 0.86 percent per year during the second. Rebleeding episodes were fatal in 78 percent of cases. These statistics, however, also reflect the outcome prior to the modern era of microsurgery and neurologic intensive care management.

One would expect these figures to have improved in recent years, but the change has not been striking. In a prospective clinical trial conducted by the International Cooperative Study in 1990 and based on observations of 3521 patients (surgery performed in 83 percent), it was found, at the 6-month evaluation, that 26 percent of the patients had died and 58 percent had made a good recovery (Kassell et al). Vasospasm and rebleeding were the leading causes of morbidity and mortality in those who survived the initial bleed.

In respect to rebleeding, all series indicate that the risk is greatest in the first day but extends for weeks. The observations of Aoyagi and Hayakawa are similar to those of other series; they found that rebleeding occurred within 2 weeks of 20 percent of patients, with a peak incidence in the 24 h after the initial episode.

**Treatment**  
This is influenced by the neurologic and general medical state of the patient as well as by the location and morphology of the aneurysm. Ideally, all patients should have the aneurysmal sac obliterated, but the mortality is high if the patient is stuporous or comatose (grade IV or V, see below). Before deciding on a course of action, it has been useful to assess the patient with reference to the widely employed scale introduced by Botterell and refined by Hunt and Hess, as follows:

Grade I. Asymptomatic or with slight headache and stiff neck
Grade II. Moderate to severe headache and nuchal rigidity but no focal or lateralizing neurologic signs
Grade III. Drowsiness, confusion, and mild focal deficit
Grade IV. Persistent stupor or semicoma, early decerebrate rigidity and vegetative disturbances
Grade V. Deep coma and decerebrate rigidity

The general medical management in the acute stage includes the following, all or in part: bed rest, fluid administration to maintain above-normal circulating blood volume and central venous pressure, use of elastic stockings and stool softeners; administration of beta blockers, calcium channel blockers, intravenous nitroprusside, or other medication to reduce greatly elevated blood pressure and then maintain systolic blood pressure at 150 mmHg or less; and pain-relieving medication for headache (this alone will often reduce the hypertension). The prevention of systemic venous thrombosis is critical, usually accomplished by the use of cyclically inflated whole-leg compression boots. The use of anticonvulsants is controversial; many neurosurgeons administer them early, with a view of preventing a seizure-induced risk of rebleeding. We have generally avoided them unless a seizure has occurred.

Calcium channel blockers are being used extensively to reduce the incidence of stroke from vasospasm. Nimodipine 60 mg, administered orally every 4 h, is currently favored. Although calcium channel blockers do not alter the incidence of angiographically demonstrated vasospasm, they have reduced the number of strokes in each of five randomized studies, beginning with the one conducted by Allen and colleagues. Several groups have been using angioplasty techniques to dilate vasospastic vessels and reporting symptomatic improvement, but there are as yet insufficient controlled data to judge the merits and safety of this procedure.

The most notable advances have been in the techniques for the obliteration of aneurysms, particularly the operating microscope and endovascular approaches, and in the management of circulatory volume. In the majority of patients intravascular volume is depleted in the days after subarachnoid hemorrhage. This, in turn, greatly increases the chances of ischemic infarction from vasospasm, though it does not alter its incidence or severity. In part, this volume contraction can be attributed to bed rest, but sodium loss, probably resulting from the release of atrial natriuretic factor (ANF), a potent oligopeptide stimulator of sodium loss in renal tubules, may also be a factor. Hyponatremia develops in the first week after hemorrhage, but it is unclear whether this also results from the natriuretic effects of ANF or is an effect of antidiuretic hormone, causing water retention. The work of Diringer and coworkers suggests that both mechanisms are operative, but we would emphasize that it is the volume depletion, not hyponatremia per se, that is of the greatest clinical consequence.

Both the risk of rerupture of the aneurysm and some of the secondary problems that arise because of the massive amount of blood in the subarachnoid space can be obviated by early obliteration of the aneurysm. Because of the changes in water balance and the risk of delayed stroke from vasospasm, there has been an emphasis on early volume expansion and sodium repletion by the intravenous infusion of crystalloids. As Solomon and Fink have pointed out, this can be accomplished with relative safety and without fear of aneurysmal rupture if blood pressure is allowed to rise only minimally. And, or course, fluid replacement and a modest elevation of blood pressure become completely safe if the aneurysm has been surgically occluded. Thus the current approach is to operate early, within 36 h if possible, on all patients in grades I and II and then to increase intravascular volume and maintain normal or above-normal blood pressures. This eliminates the risk of rebleeding, with its high mortality, and helps prevent the second cause of morbidity, stroke from vasospasm. The timing of surgery or endovascular treatment for grade III patients is still controversial, but if their medical condition allows, they too probably benefit from the same early and aggressive approach. In grade IV patients, the outcome is generally dismal, no matter what course is taken, but we have usually counseled against early operation; some neurosurgeons disagree. The insertion of ventricular drains into both frontal horns has occasionally raised a patient with severe hydrocephalus to a better grade and facilitated early operation. In the
hands of experienced anesthesiologists and cerebrovascular surgeons, the operative mortality, even in grade III and IV patients, has now been reduced to 2 to 3 percent. For a detailed account of the operative approach to each of the major classes of saccular aneurysm, the reader is referred to the monograph by Ojemann and colleagues.

Several alternative therapeutic measures are still being studied. Among these, endovascular obliteration of the lumen of the aneurysm holds the most promise. This has become the preferred approach for aneurysms that are surgically inaccessible—for example, those in the cavernous sinus—or for patients whose medical state precludes an operation. Among several trials that have compared surgery with endovascular placement of coils in the aneurysm, several have shown a slight superiority of the latter. For example, the International Subarachnoid Aneurysm Trial Group randomly assigned over 2000 patients to surgery or platinum coil placement; the overall rate of death or dependence at 1 year was 24 percent in the endovascular group and 31 percent in the operated group. Doubtless, further studies will continue to clarify the relative benefits of the treatment. We would comment that the skill of the surgeon and the quality of postoperative care are major determinants of outcome; perhaps the simplicity of endovascular treatment and the improvements in the training of interventional specialists will prove its advantage over time.

Because of the current approach of ablating the aneurysm early, the previously popular use of antifibrinolytic agents as a means of impeding lysis of the clot at the site of aneurysmal rupture has been generally abandoned. Repeated drainage of the CSF by lumbar puncture is no longer practiced as a routine. One lumbar puncture is generally carried out for diagnostic purposes if the CT scan is inconclusive; thereafter spinal fluid drainage is performed only for the relief of intractable headache or to detect recurrence of bleeding. As mentioned earlier, patients with stupor or coma who have massive hydrocephalus often benefit from decompression of the ventricular system. This is accomplished initially by external drainage and may require permanent shunting if the hydrocephalus returns. The risk of infection of the external shunt tubing is high if it is left in place for much more than 3 days. Replacement with a new tube, preferably at another site, reduces this risk.

Unruptured Intracranial Aneurysms Not infrequently, cerebral angiography, MRI, MRA, or CT scanning performed for an unrelated reason, discloses the presence of an unruptured saccular aneurysm. Or, a second or third aneurysm is found during the angiogram to assess a ruptured one. There is now a reasonable body of information about the natural history of these lesions. Wiebers and colleagues observed 65 patients with one or more unruptured aneurysms for at least 5 years after their detection. The only clinical feature of significance relative to rupture was aneurysmal size. None of 44 aneurysms smaller than 10 mm in diameter had ruptured, whereas 8 of 29 aneurysms 1 cm or larger eventually did so, with a fatal outcome in 7 cases. Two large studies have attempted to refine these statistical data. In the older Cooperative Study of Intracranial Aneurysms, none of the aneurysms less than 7 mm diameter “had further trouble.” A more recent and quite sizable cooperative study that included 4060 patients and gathered data prospectively for 5 years, conducted by the International Study of Unruptured Intracranial Aneurysms Investigators, found an extremely low rate of rupture, about 0.1 percent yearly, for aneurysms smaller than 7 mm in diameter, an annual risk of 0.5 percent was found for aneurysms between 7 and 10 mm, and a risk ranging from 0.6 to 3.5 percent for lesions between 13 and 24 mm (depending on location). The risk ranged up to 10 percent for aneurysms greater than 25 mm diameter. The yearly rates for rupture were higher in all categories if there had been prior bleeding from another site. The location of the lesion also had great bearing on the risk of rupture, as did increasing age; notably, vertebrobasilar and posterior cerebral aneurysms bled at a rate many times higher than the others. The importance of such data is underscored by the comparison to the risk of surgery and endovascular treatment, which begin to exceed the risk of bleeding within 5 years in the smaller aneurysms located in the carotid circulation.

Giant Aneurysms As has been stated, these are believed to be congenital anomalies even when there is considerable atherosclerosis in their walls. They may become enormous in size, by definition greater than 2.5 cm in diameter, but sometimes twice or more as large. Most are located on a carotid, basilar, anterior, or middle cerebral artery. They grow slowly by accretion of blood clot within their lumens or by the organization of surface blood clots from small leaks. At a certain point they may compress adjacent structures, e.g., those in the cavernous sinus, optic nerve, or lower cranial nerves. The giant fusiform aneurysm of the midbasilar artery, with signs of brainstem ischemia and lower cranial nerve palsies, is a relatively common form. Clotting within the aneurysm may cause ischemic infarction in its territory of supply. Giant aneurysms may rupture and cause subarachnoid hemorrhage, but not nearly as often as saccular aneurysms. This clinical observation has been confirmed by the International Study, referred to above.

Treatment is surgical if the lesion is symptomatic and it is accessible; treatment is with endovascular techniques if the lesion is in the vertebral or midbasilar artery. Obliteration of the lumen, coupled with vascular bypass procedures, has been successful in the hands of a few cerebrovascular neurosurgeons, but the morbidity is high. Some aneurysms can be ligated at their necks, others by trapping or by the use of an intravascular detachable balloon. Drake has summarized his experience in the treatment of 174 such cases. Ojemann and colleagues have also had singular success in treating these lesions by a combination of surgical techniques; in more than 40 cases, half of them trapped and half obliterated, there was not a single fatality. Some have been wrapped in muscle or similar material with mixed results. We have followed one such patient operated by T. Sundt over 25 years ago. Recent attempts at stabilizing the expansion of the aneurysm by stenting are under study.

Arteriovenous Malformations of the Brain

An arteriovenous malformation (AVM) consists of a tangle of dilated vessels that form an abnormal communication between the arterial and venous systems, really an arteriovenous fistula. It is a developmental abnormality representing persistence of an embryonic pattern of blood vessels and is not a neoplasm, but the constituent vessels may proliferate and enlarge with the passage of time. Arteriovenous malformations have been designated by a number of other terms, such as angioma and arteriovenous aneurysm, but these are less appropriate; angioma suggests a tumor, and the term aneurysm is generally reserved for the lesions described in the preceding section. Venous malformations, consisting purely of distended veins deep in the white matter, are a separate entity;
they may be the cause of seizures and headaches but seldom of hemorrhage. When a small hemorrhage occurs in relation to venous malformation, it is usually due to an associated cavernous malformation.

Vascular malformations vary in size from a small blemish a few millimeters in diameter lying in the cortex or white matter to a huge mass of tortuous channels constituting an AV shunt of sufficient magnitude, in rare instances, to raise cardiac output. Hypertrophic dilated arterial feeders can be seen approaching the main lesion and to break up into a network of thin-walled blood vessels that connect directly with draining veins. The latter often form greatly dilated, pulsating channels, carrying away arterial blood. The tangled blood vessels interposed between arteries and veins are abnormally thin and do not have the structure of normal arteries or veins. Arteriovenous malformations occur in all parts of the cerebrum, brainstem, and cerebellum (and spinal cord), but the larger ones are more frequently found in the central part of a cerebral hemisphere, commonly forming a wedge-shaped lesion extending from the cortex to the ventricle. Some lie on the dural surface of the brain or spinal cord, but these most often turn out to be direct arteriovenous fistulas, as discussed further on.

When hemorrhage occurs, blood may enter the subarachnoid space, producing a picture almost identical to that of ruptured saccular aneurysm, but generally less severe; since most AVMs lie within cerebral tissue, bleeding is more than likely to be intracerebral as well, causing a hemiparesis, hemiplegia, and so forth, or even death.

Arteriovenous malformations are about one-tenth as common as saccular aneurysms and about equally frequent in males and females. The two lesions—AVM and saccular aneurysm (on the main feeding artery of the AVM)—are associated in about 5 percent of cases; the conjunction increases with the size of the AVM and the age of the patient (Miyasaka et al). Rarely, AVMs occur in more than one member of a family in the same generation or successive ones.

For a review of the embryologic theories of formation of AVMs, the reader is directed to the article by Fleetwood and Steinberg.

Clinical Features  Bleeding or seizures are the main modes of presentation. Most AVMs are clinically silent for a long time, but sooner or later they bleed. The first hemorrhage may be fatal, but in more than 90 percent of cases the bleeding stops and the patient survives. The rate of hemorrhage in untreated patients is established to be 2 to 4 percent per year, far lower than for aneurysms. The mortality rate in two major series (Crawford et al, Ondra et al) has been 1 to 2 percent per year but as high as 6 to 9 percent in the immediate year following a first hemorrhage. The matter of an increased risk of AVM rupture during pregnancy has been disputed. The weight of evidence suggests that the risk is not raised by pregnancy alone, but—as with saccular aneurysm—that parturition and Valsalva activity is always a source of concern. Before rupture, chronic, recurrent headache may be a complaint; usually the headache is of a nondescript type, but a classic migraine with or without neurologic accompaniment occurs in about 10 percent of patients—probably with greater frequency than it does in the general population. Most of the lesions associated with migraine-like headaches lie in the parieto-occipital region of one cerebral hemisphere, and about two-thirds of such patients have a family history of migraine.

Huge AVMs may produce a slowly progressive neurologic deficit because of compression of neighboring structures by the enlarging mass of vessels and by shunting of blood through greatly dilated vascular channels (“intracerebral steal”), resulting in hypoperfusion of the surrounding brain (Homan et al). When the vein of Galen is enlarged as a result of drainage from an adjacent AVM, hydrocephalus may result. Not infrequently one or both carotid arteries pulsate unusually forcefully in the neck. A systolic bruit heard over the carotid in the neck or over the mastoid process or the eyeballs in a young adult is almost pathognomonic of an AVM. However, such bruits have been heard in fewer than 25 percent of our patients. Exercise that increases the pulse pressure may bring out a bruit if none is present at rest.

The blood pressure may be elevated or normal; it is axiomatic that the occurrence of intracranial bleeding with a previously normal blood pressure should raise the suspicion of an AVM, but also of ruptured saccular aneurysm, bleeding diathesis, cerebral vessel amyloidosis, or hemorrhage into a tumor. Rarely, inspection of the eye grounds discloses a retinal vascular malformation that is coextensive with a similar lesion of the optic nerve and basal portions of the brain. Cutaneous, orbital, and nasopharyngeal AVMs may occasionally be found. Rarely, skull films show crescentic linear calcifications in the larger malformations.

The natural history of AVMs has been studied by Ondra and colleagues, who have presented data on a large and comprehensive series of untreated malformations in Finland over a 30-year period, and another similar series has been reported by Crawford and coworkers in Great Britain. In the latter study, comprising 343 patients, 217 were managed without surgery and observed for many years (mean, 10.4 years). Hemorrhage occurred in 42 percent and seizures in 18 percent. By 20 years after diagnosis, 29 percent had died and 27 percent of the survivors had a neurologic handicap. Although the lesion is present from birth, onset of symptoms is most common between 10 and 30 years of age; occasionally it is delayed to age 50 or even beyond. In almost half of patients, the first clinical manifestation is a cerebral subarachnoid hemorrhage; in 30 percent, a seizure is the first and only manifestation; and in 20 percent, the only symptom is headache. Progressive hemiparesis or other focal neurologic deficit is present in about 10 percent of patients. In a series of 1000 patients referred mainly for proton beam radiation of an AVM and studied by our colleague R. D. Adams, 464 had a hemorrhage as the first manifestation and 218 had a seizure (mainly with frontal and frontoparietal lesions). In 139, the lesion came to attention as a result of a progressive neurologic deficit; most of these were situated in the posterior fossa or axially in the cerebral. Headaches were an early symptom in 212, but only 59 of these patients had a subsequent hemorrhage. The combination of a prolonged history of headaches, seizures, and a progressive deficit almost always indicated a large malformation.

Fully 95 percent of AVMs are disclosed by CT scans if enhanced and an even larger number by MRI (Fig. 34-25). Magnetic susceptibility MRI shows small areas of previous bleeding around AVMs. Arteriography is usually necessary to establish the diagnosis with certainty and will demonstrate AVMs larger than 5 mm in diameter (Fig. 34-26); MRI may fail to reveal smaller lesions. Small ones may be obscured by hemorrhage; even at autopsy, a careful search under the dissecting microscope may be necessary to find them.

Treatment  The preferred approach in most centers is surgical excision. Some 20 to 40 percent of AVMs are amenable to block dissection, with an operative mortality rate of 2 to 5 percent and a morbidity of 5 to 25 percent (see Fleetwood and Steinberg for a
summary of reported surgical results up to 2002). In the others, which are inaccessible, attempts have been made to obliterate the malformed vessels by ligation of feeding arteries or by the use of endovascular embolization with liquid adhesives or particular ma-

terial that are injected via a balloon catheter that has been navigated into a feeding vessel. Complete obliteration of large AVMs is usually not possible by these methods but, they are highly effective in reducing the size of the AVM prior to surgery.

Kjellberg and Chapman pioneered the treatment of AVMs at the Massachusetts General Hospital using a single dose of subnecrotizing stereotactically directed proton radiation. The technique of radiosurgery has been adopted by others using photon radiation sources, such as a linear accelerator, gamma knife, and other modes of focused x-ray radiation, as an accepted alternative to operative treatment of lesions situated in deep regions, including the brainstem, or in "eloquent" areas of the cortex. Generally, malformations smaller than 3 cm diameter are treatable in this way. Radiosurgical obliteration of AVMs occurs in a delayed manner, usually with a latency of at least 18 to 24 months after treatment. During this early period the patient is unprotected from rebleeding.

The likelihood of successful treatment and the nature of the risks depend on the location and size of the AVM and the radiation dose delivered. After 2 years, 75 to 80 percent of AVMs smaller than 2.5 cm in diameter have been obliterated. Even for those AVMs that have not been totally eliminated, the radiation effect appears to confer some long-term protection from bleeding. Of the larger ones, a majority are shrunken or appear less dense. The rest have shown no change at this low dose level, but even in this group, the morbidity and mortality are lower than in the untreated group. However, a proportion of larger AVMs that are obliterated will recanalize, and many of these will subsequently bleed. Among more than 250 patients whose AVMs disappeared following proton beam therapy, there has been no recurrence of hemorrhage for up to 10 years; in larger AVMs (approximately the last 1000

Figure 34-25. A. Left temporal arteriovenous malformation (AVM), demonstrated by MRI. The patient was a 59-year-old woman with long-standing complaints of headache. B. Arteriogram showing large feeding and draining vessels and the characteristic vascular blush of the malformation.

Figure 34-26. Top: Angiogram of a large parieto-occipital AVM prior to treatment showing the malformation and greatly enlarged draining veins. Bottom: Obliteration of the malformation 2 years after proton beam treatment.
cases) treated in this way, the frequency and severity of hemorrhage have been significantly reduced. The results of treatment with focused gamma radiation have been about the same. In one study, the risk of hemorrhage was reduced by 54 percent between the time of radiation and obliteration of the malformation and by 88 percent thereafter (Maruyama et al).

Two types of complications of radiation occur at a combined rate of approximately 2 to 4 percent. The first is delayed radiation necrosis, which is predictable based on the radiation dose, and the second is a venous congestion that occurs several weeks or months after treatment. The latter is indicative of the desired effect of thrombosis of the malformation. Both cause local symptoms for weeks or months. Radiation necrosis may be reduced by the administration of corticosteroids but the vascular problem generally is not helped.

The treatment of AVMs by endovascular techniques is increasingly popular but has not been fully evaluated. Nearly every AVM has several feeding arteries, some not reachable by catheter, and some part of the AVM remains after treatment. In most series, 25 percent or more of AVMs, mostly of small and medium size, could be completely obliterated, with a mortality rate below 3 percent and morbidity of 5 to 7 percent, which compares favorably with surgical outcomes. These techniques are also particularly well adapted to lesions of a combined AVM and an aneurysm on the feeding vessel.

Most recently, combined therapy begins with endovascular reduction of the lesion and is followed by either surgery or radiation has been viewed most favorably. In series of patients using this approach, over 90 percent of lesions could be obliterated with a very low rebleeding rate over several years. What is clear is that the plan for each patient must be individualized based on the size, location, nature of feeding vessels, the presence of other vascular lesions (aneurysm or additional AVM), and the age of the patient. Even then, there will be differences of opinion based on local resources and experience.

Finally, if the primary problem is recurrent seizure, successful treatment with reduction or cessation of seizures is achieved in a very high proportion of cases. The results are comparable to those from surgery and radiation, even if the AVM is not entirely obliterated.

**Dural Arteriovenous Fistulas**

These curious vascular abnormalities, occurring in both the cranial and spinal dura, have different presentations at each site; the latter form is discussed with other diseases of the spinal cord in Chap. 46. The cranial type is being detected with increasing frequency as refinements continue to be made in imaging of the cerebral vessels, but its true incidence and pathogenesis are not fully known. The defining features are radiologic—a nidus of abnormal arteries and veins with arteriovenous shunting contained entirely within the leaflets of the dura. The lesion is fed by dural arterial vessels derived from the internal cranial circulation and often, more prolifically, from the external cranial circulation (external carotid artery and muscular branches of the vertebral artery). The venous drainage is complex and is largely into the dural venous sinuses (Fig. 34-27). The rapid transit of injected angiographic dye through these fistulas accounts for the early opacification of the draining venous structures; in the case of high-flow connections, this may not be seen unless images are taken almost immediately after the injection. A number of potential feeding vessels must be injected to demonstrate all the conduits into the lesion. On CT scanning and MRI, the fistula is sometimes detected as a thickening or enhancement of a region of dura, generally close to a large dural venous sinus. In other cases, the dilated draining vessels may be seen only with the injection of dye or gadolinium. Probably, many are not detected by these techniques.

The origin of these vascular lesions has not been settled—several mechanisms may be involved. Most evidence suggests that some of these lesions, unlike conventional cerebral AVMs and aneurysms, are not developmental in origin. The best-defined examples are those that arise adjacent to a venous sinus thrombosis or in association with a vascular atresia, most often in the transverse sigmoid sinus or adjacent to the cavernous sinus. However, it is not clear whether the abnormality of the dural sinus is the cause or the result of the dural fistula. In a number of cases, a dural fistula has appeared after a forceful head injury, often in a region remote from the site of impact. A small group is associated with the Klippel-Trenaunay or Osler-Weber-Rendu syndromes, diseases in which a frequent conjunction with AVMs is well known. Usually, all of these causes can be excluded and the largest group remains idiopathic.

A major obstacle to our understanding of the dural AVM has been the varied and confusing ways in which this lesion presents clinically. Subdural hemorrhage is an infrequent mode of presentation, sometimes creating a large and fatal clot; another syndrome is a cerebral-subarachnoid hemorrhage, although this occurs with not nearly the frequency or severity as bleeding from brain AVMs. However, our knowledge of the risk of bleeding from dural fistulas and the evolution of the lesions is far less precise than it is for cerebral AVMs. It appears that the dural lesions most at risk of bleeding are those located in the anterior cranial fossa and at the tentorial incisura. Seizures are distinctly uncommon. A special syndrome linked to dural AVMs, although it may occur also with high-flow cerebral malformations, is of headache, vomiting, and papilledema—namely, *pseudotumor cerebri* (Chap. 30). A cranial bruit is infrequent. In small children, the high-flow lesions may shunt so much blood as to cause congestive heart failure, similar to malformations of the vein of Galen.

Treatment is by surgical extirpation or endovascular embolization, a painstaking procedure because of the multitude of poten-
Cavernous Malformations

Vascular malformations composed mainly of clusters of thin-walled veins without important arterial feeders and with little or no intervening nervous tissue make up a significant group, some 7 to 8 percent of our series of AVMs. Conventional subdivisions of this group into cavernous, venous, and telangiectatic types have not proven useful. We have, therefore, roughly designated them all as cavernous. They have several attributes that set them apart. Their tendency to bleed is probably no less than that of the more common AVMs, but far more often the hemorrhages are small and clinically silent. The exact incidence of bleeding is uncertain but is estimated to be less than 1 percent per year per lesion. Often there are multiple lesions. They are generally not seen in arteriograms. The diagnosis is based on their clinical manifestations and MRI, which discloses a cluster of vessels surrounded by a zone of hypodense ferritin in the T1-weighted images (Fig. 34-28), the product of previous small episodes of bleeding. A small but uncertain number are associated with adjacent venous malformations, visualized by imaging studies. The lack of formation of a mass over a long period of time separates this lesion from a malignant tumor that has bled. About one-half of all cavernous angiomas lie in the brainstem, and in the past (before the availability of MRI), many of them were misdiagnosed as multiple sclerosis because of a stepwise accumulation of neurologic deficits with each hemorrhage.

About 10 percent of these lesions are multiple and 5 percent are familial. In one of the families we have followed of Italian-American origin, there were 29 affected members in three generations. The inheritance followed an autosomal dominant pattern; Marchuk and coworkers have localized the abnormal gene in other kindreds to the long arm of chromosome 7. One interesting characteristic of this group, as pointed out by Labauge and colleagues, is the appearance over time of new lesions in one-third of patients. The follow-up of some of our patients has documented this.

Treatment  Cavernous angiomas on the surface of the brain, within reach of the neurosurgeon, even those in the brainstem, can be plucked out, like clusters of grapes, with low morbidity and mortality. Kjellberg and colleagues have treated 89 deeply situated cavernous angiomas with low-dose proton radiation. Our impression is that these vascular malformations, like the hemangioblastoma, respond poorly to radiation and are not amenable to treatment by endovascular techniques.

Lesions that cause recurrent bleeding and are surgically accessible with little risk are often removed, but incidentally discovered angiomas and those that are inaccessible may be left alone. Although this is the approach usually taken, there is not adequate data on the rate and risk of bleeding to determine the proper approach.

Other Causes of Intracranial Bleeding

Next to hypertension, anticoagulant therapy is currently the most common cause of cerebral hemorrhage. The hemorrhages that develop, though sometimes situated in the sites of predilection of hypertensive hemorrhage, are more likely to occur elsewhere, mainly in the lobes of the brain. When the bleeding is precipitated by warfarin therapy, treatment with fresh-frozen plasma and vitamin K is recommended; when bleeding is associated with aspirin therapy or other agents that affect platelet function, fresh platelet infusion, often in massive amounts, is required to control the hemorrhage. The use of thrombolytics in the treatment of stroke is complicated by intracranial hemorrhage in 6 to 20 percent of cases, depending on the dose and timing of drug administration after the onset of symptoms, as discussed on page 694.

In the elderly, amyloid angiopathy appears to be a major cause of lobar hemorrhages, especially if they appear in succession or are multiple. Several of our patients have had minor head injuries in
the weeks before hemorrhage. In our own material, only severe impregnation of vessels with amyloid and fibrinoid change in the vessel wall were associated with hemorrhage (Vonsattel et al.). Greenberg and colleagues have found that apolipoprotein E4, the same marker that is overrepresented in Alzheimer disease, is associated with severe amyloid angiopathy and intracerebral hemorrhage, but others have found an association with the E2 allele. Contrary to previous notions, there is probably no greater risk in evacuating these clots surgically than in the case of other cerebral hemorrhages, but most of them are of a size that allows conservative management.

Several primary hematologic disorders are also complicated by hemorrhage into the brain. The most frequent of these are leukemia, aplastic anemia, and thrombocytopenic purpura. Often they give rise to multiple intracranial hemorrhages, some in the subdural and subarachnoid spaces. As a rule, this complication signals a fatal issue. Other, less common causes of intracerebral bleeding are advanced liver disease, uremia being treated with dialysis, and lymphoma. Usually several factors are operative in these hematologic cases: reduction in prothrombin or other clotting elements (fibrinogen, factor V), bone marrow suppression by antineoplastic drugs, and disseminated intravascular coagulation. Any part of the brain may be involved, and the hemorrhagic lesions are usually multiple. Frequently there is also evidence of abnormal bleeding elsewhere (skin, mucous membranes, kidney) by the time cerebral hemorrhage occurs. Plasma exchange, used in the treatment of myasthenia gravis and Guillain-Barré disease, also lowers the serum fibrinogen level. Despite its marked degree, but we have not observed a single instance of intracerebral hemorrhage in more than 500 patients treated in this way.

Acute extradural and subdural hemorrhage, typically traumatic in origin, must also be considered in the patient who, under unknown circumstances, has rather abruptly developed a neurologic deficit such as hemiparesis or confusion, with or without bloody CSF. The use of anticoagulant drugs and intrinsic coagulopathies of all types are risks for these extracerebral hemorrhages. In chronic subdural hemorrhage, which can occur without remembered trauma, the indefinite picture of drowsiness, headache, confusion, and mild hemiparesis may erroneously be attributed to a stroke, especially in elderly persons. There should be no hesitation in subjecting patients to CT scanning whenever the diagnosis of subdural hemorrhage cannot readily be excluded on clinical grounds. In the patient who falls and strikes his head at the onset of a stroke, it may be difficult or impossible to decide whether blood in the CSF is due to the stroke or to cerebral contusion. These disorders are discussed more fully in the next chapter.

Occasionally the origin of intracranial hemorrhage cannot be determined clinically or pathologically. In some postmortem cases, a careful search under the dissecting microscope discloses a small arteriovenous malformation; this is the basis for suspecting that an overlooked lesion of this type may be the cause of cerebral hemorrhage in other cases. Primary intraventricular hemorrhage, a rare event in adults, can sometimes be traced to a vascular malformation or neoplasm of the choroid plexus; more often, such a hemorrhage is the result of periventricular bleeding, in which blood enters the ventricle without producing a visible parenchymal clot.

Hemorrhage into primary and secondary brain tumors is not rare; when this is the first clinical manifestation of the neoplasm, diagnosis may be difficult. Choriocarcinoma, melanoma, renal cell and bronchogenic carcinoma, pituitary adenoma, thyroid cancer, glioblastoma multiforme, intravascular lymphoma, and medulloblastoma may present in this way. Careful inquiry will usually disclose that neurologic symptoms compatible with intracranial tumor growth had preceded the onset of hemorrhage. Needless to say, a thorough search should be made in these circumstances for evidence of intracranial tumor or of secondary tumor deposits in other organs, particularly the lungs.

The term mycotic aneurysm designates an aneurysm caused by a localized bacterial or fungal inflammation of an artery (Osler introduced the term mycotic to describe endocarditis, but its proper current use is to describe fungal infection). With the introduction of antibiotics, mycotic aneurysms have become less frequent, but they are still being seen in patients with bacterial endocarditis and in intravenous drug abusers. Peripheral arteries are involved more often than intracranial ones; about two-thirds of the latter are associated with subacute bacterial endocarditis due to streptococcal infections. In recent years, the number of mycotic aneurysms due to staphylococcal infections and acute endocarditis appears to have increased. The usual pathogenic sequence is an embolic occlusion of a small artery, which may become itself clinically by an ischemic stroke, with cells in the CSF. Later, or as the first manifestation, the weakened vessel wall gives way and causes a subarachnoid or brain hemorrhage. The mycotic aneurysm may appear on only one artery or several arteries, and the hemorrhage may recur. A consensus regarding the treatment of mycotic aneurysm has not been reached. The underlying endocarditis or septicemia mandates appropriate antibiotic therapy and, in at least 30 percent of cases, healing of the aneurysm can be observed in successive arteriograms with this approach alone. Treatment should continue for at least 6 weeks. Some neurosurgeons believe in excising an accessible aneurysm if it is solitary and the systemic infection is under control. Some mycotic aneurysms do not bleed, and in our view medical therapy takes precedence over surgical therapy.

The pathologic entity called brain purpura (pericapillary encephalorhagia), incorrectly referred to as “hemorrhagic encephalitis,” consists of multiple petechial hemorrhages scattered throughout the white matter of the brain. The clinical picture is that of a diffuse encephalopathy, but diagnosis is essentially pathologic. Blood does not appear in the CSF, and the condition should not be confused with a stroke. It is virtually impossible to establish the diagnosis during life, but the pathologic appearance is unique and highly characteristic. The lesions in brain purpura are always small, 0.1 to 2.0 mm in diameter, and are confined to the white matter, particularly the corpus callosum, centrum ovale, and middle cerebellar peduncles. Each lesion is situated around a small blood vessel, usually a capillary. In this para-adventitial area, both the myelin and axis cylinders are destroyed, and the lesion is usually though not always hemorrhagic. Fibrin exudation, perivascular and meningeal infiltrates of inflammatory cells, and widespread necrosis of tissue are not observed. In these respects brain purpura differs fundamentally from acute necrotizing hemorrhagic leukoencephalitis. Usually the patient becomes stuporous and comatose without focal neurologic signs, and the CSF is normal. The etiology of brain purpura is quite obscure. It may complicate viral pneumonia, uremia, arsenical intoxication, and, rarely, metabolic encephalopathy and sepsis, or there may be no associated disease.

A degree of hemorrhage is to be expected in acute hemorrhagic leukoencephalitis (Hurst type), which represents an extreme form of acute disseminated encephalomyelitis (Chap. 36), and in herpes encephalitis (Chap. 33).

Inflammatory diseases of arteries and veins, especially polyarteritis nodosa, lupus erythematosus, and moyamoya disease, are
Hypertensive encephalopathy may complicate hypertension from any cause (chronic renal disease, renal artery stenosis, acute glomerulonephritis, acute toxemia, pheochromocytoma, Cushing syndrome), cocaine, or administration of drugs such as amino-
phyline or phenylephrine, but it occurs most often in patients with rapidly worsening “essential” hypertension.

In eclampsia, which may be considered a special form of hypertensive encephalopathy, and in acute renal disease, particularly in children, encephalopathic symptoms may develop at blood pressure levels considerably lower than those of hypertensive encephalopathy of “essential” type. In eclampsia, the retinal and cerebral lesions are the same as those that complicate malignant nephrosclerosis; in both there is also failure of autoregulation of the cerebral arterioles. In the pathogenesis of pre-eclampsia, inhibition of an endothelium-derived relaxing factor by hemoglobin has been postulated by Sarrel and colleagues. See page 291 for a discussion of eclamptic seizures.

Laboratory Features Hypertensive encephalopathy is marked by characteristic changes on CT scanning and MRI. The radiologic findings are often misinterpreted as large areas of infarction or demyelination, but their tendency to normalize over several weeks is remarkable. As summarized by Hauser and coworkers, the main finding is a bilateral increase in T2 signal intensity in the white matter on MRI and a corresponding reduced density (edema) on CT, usually concentrated in the posterior part of the hemispheres (Fig. 34-29). This condition is one of the causes of reversible posterior leukoencephalopathy. These imaging characteristics are due to an accumulation of fluid, but—unlike the edema in trauma, neoplasm, or stroke—there is little or no mass effect and the water does not tend to course along white matter tracts such as the corpus callosum. In addition, scattered cortical lesions occur in a watershed distribution and probably correspond to small infarctions. These same findings in the white matter and cortex occur in eclampsia (Fig. 34-30) and have been seen in cases of diffuse vasospasm due to sympathomimetic and serotoninergic drugs, discussed further on.

Finally, it should be mentioned that hypertensive encephalopathy and eclampsia have at times caused subarachnoid hemorrhage. Most such cases are not due to the rupture of an intracranial aneurysm and are not as overwhelming as in the latter case; indeed, the headache associated with this form of hemorrhage tends to be much milder than with aneurysmal rupture and it may even be absent. Most often the bleeding is mainly a feature of the radiologic examination of the brain as described by Shah. The mechanism is obscure.

In many but not all the cases, the CSF pressure and protein values are elevated, the latter to more than 100 mg/dL in some instances, but there is no cellular reaction.

Pathophysiology Neuropathologic examination reveals a rather normal-looking brain, but in some cases cerebral swelling, hemorrhages of various sizes, or both will be found. In extreme cases, a cerebellar pressure cone reflects an increased volume of tissue and increased pressure in the posterior fossa; in rare instances lumbar puncture appears to have precipitated fatalities. Microscopically there are widespread minute infarcts in the brain (with a predilection for the basis pontis), the result of fibrinoid necrosis of the walls of arterioles and capillaries and occlusion of their lumens by fibrin thrombi (Chester et al). This is often associated with zones of cerebral edema. Similar vascular changes are found in other organs, particularly in the retinae and kidneys.

Volhard originally attributed the symptoms of hypertensive encephalopathy to vasospasm. This notion was reinforced by Byrom, who demonstrated, in rats, a segmental constriction and dil-

Clinical Features

Hypertensive encephalopathy is the term applied to a relatively rapidly evolving syndrome of severe hypertension in association with headache, nausea and vomiting, visual disturbances, confusion, and—in advanced cases—stupor and coma. Multiple seizures are frequent and may be more marked on one side of the body than the other. These symptoms of diffuse cerebral disturbance may be accompanied by focal or lateralizing neurologic signs, either transitory or lasting, which should always suggest cerebral hemorrhage or infarction, i.e., the more common cerebrovascular complications of severe chronic hypertension. A clustering of multiple microinfracts and petechial hemorrhages (the basic neuropathologic changes in hypertensive encephalopathy) in one region may rarely result in a mild hemiparesis, aphasic disorder, or rapid failure of vision. By the time the neurologic manifestations appear, the hypertension has usually reached the malignant stage, with diastolic pressures above 125 mmHg, retinal hemorrhages, appear, the hypertension has usually reached the malignant stage, rapid failure of vision. By the time the neurologic manifestations region may rarely result in a mild hemiparesis, aphasic disorder, or neuropathologic changes in hypertensive encephalopathy) in one.
Hypertensive encephalopathy in a 55-year-old woman with headache and a single seizure. The characteristic changes of excess water in large regions of the white matter are seen on the CT scan (left panel) and in a T2-weighted MRI (right panel). The areas of signal change are associated with little mass effect and tend to be concentrated in the posterior regions of the brain. Other small cortical and subcortical lesions are common in watershed areas. There may be associated heterogeneous infarctions in the cerebral cortex, as shown in the following figure. The same changes in the occipital white matter may occur in eclampsia and from other causes of "posterior leukoencephalopathy" (see also page 1040).

Figure 34-29. Hypertensive encephalopathy in a 55-year-old woman with headache and a single seizure. The characteristic changes of excess water in large regions of the white matter are seen on the CT scan (left panel) and in a T2-weighted MRI (right panel). The areas of signal change are associated with little mass effect and tend to be concentrated in the posterior regions of the brain. Other small cortical and subcortical lesions are common in watershed areas. There may be associated heterogeneous infarctions in the cerebral cortex, as shown in the following figure. The same changes in the occipital white matter may occur in eclampsia and from other causes of "posterior leukoencephalopathy" (see also page 1040).

MRI T2 signal changes in eclampsia. Most of the vascular changes and edema are situated in the cortical watershed distributions between the middle and an anterior cerebral arteries. These imaging findings were transient, as was mild signal change in the occipital subcortical regions, the latter being typical of hypertensive encephalopathy, as in Fig. 34-29.

Lowering of the blood pressure with antihypertensive drugs may reverse the picture in a day or two. In the past, when effective antihypertensive drugs were not available, the outcome was often fatal. The BUN is only slightly elevated except in cases of renal failure, and the usual patient is not uremic. The same can be accomplished by administering magnesium sulfate in the eclamptic woman. Treatment consists of measures that promptly reduce arterial blood pressure, but antihypertensive drugs must be used cautiously; a safe target is a pressure of 150/100 mmHg. One may use intravenous sodium nitroprusside, 0.5 to 0.8 mg/kg/min; a calcium channel blocker such as nifedipine, 10 to 20 mg sublingually; or intravenous beta-adrenergic blockers (labetalol, 20 to 40 mg intravenously followed by an infusion at 2 mg/min, or esmolol are favored). These must be followed by longer-acting antihypertensive agents such as ACE inhibitors or calcium channel blockers.
If there is already evidence of brain edema and increased intracranial pressure, dexamethasone, 4 to 6 mg every 6 h, is usually added, but its effect, and the use of hyperosmolar therapy, have not been studied systematically; our clinical impression is that they have little effect.

**Diffuse and Focal Cerebral Vasospasm**

A focal reduction in the caliber of the basal vessels and their proximal branches is a well-known complication of subarachnoid hemorrhage, as described on page 718. Vasospasm has also been implicated in migraine and migrainous stroke and as an explanation for TIAs, but with little supportive evidence. Some degree of attenuation of large cerebral vessels is observed in hypertensive encephalopathy, in eclampsia, and with adrenergic drug use (e.g., phenylpropanolamine, cocaine, “triptan” drugs used for the treatment of migraine), but the role of the vascular changes in causing strokes has never been clear. A related condition of cerebral vasculitis caused by sympathomimetic drugs is discussed further on, with other vasculitides. The problem of stroke with migraine, which has a complex and uncertain relationship to vasospasm, is discussed on page 151.

In addition to these disorders of known causation, Call and colleagues have described a striking idiopathic widespread segmental vasospasm of cerebral vessels characterized by severe headache and fluctuating TIA-like episodes (all cases drawn from our hospital services; termed Call-Fleming syndrome in some publications). The middle cerebral arterial and its branches are mainly affected; the angiographic appearance may be mistaken for arteritis. A number of similar cases have been described, and we have seen several that resulted in a small stroke. There may be a posterior leukoencephalopathy that is similar to the imaging appearance in hypertensive encephalopathy. Sometimes the headache is minimal. The nature of this condition of idiopathic diffuse vasospasm is unknown. A relationship to hypertensive encephalopathy or to delayed postpartum eclampsia has been suggested, because of the aforementioned white matter changes and the observation of widespread vasospasm in eclamptic women. The patients have seen with this process, after several weeks of dramatically fluctuating focal neurologic symptoms and disabling headache, have recovered completely or nearly so. In all likelihood, several disorders cause this type of vasculopathy. Calcium channel blockers or corticosteroids have been prescribed, but their effectiveness cannot be determined. There are clinical similarities to the syndrome of migraine, transient focal deficits, and CSF pleocytosis described on page 152; the spinal fluid in the vasospasm cases is, however, normal.

It has recently been brought to attention—by Singh and colleagues and others—that the use of serotonergic drugs may produce a similar syndrome of reversible multifocal vasospasm, severe headache, and stroke. One of their three patients was using the antimigraine medicine sumatriptan; the other two were using serotonin reuptake inhibitor antidepressants and, in addition, had taken over-the-counter cold remedies that included pseudophedrine and dextromethorphan; we are aware of other similar cases. These authors proposed that in these cases a “serotonin syndrome” had occurred, similar to what has been seen with overdoses of this class of antidepressants.

It has been suspected that the same sort of vasculopathy is produced by sympathomimetic drugs alone, such as ephedra in health food supplements, phenylpropanolamine, pseudophedrine, and cocaine, but there are few well-studied cases. These are discussed below, under “Arteritis Symptomatic of Underlying Systemic Disease and Sympathomimetic Drug Reactions.” In all cases, including those noted above, the treatment is cessation of the offending drugs; nitroglycerin, nitroprusside, or beta-adrenergic infusions have been tried with uncertain effect.

**INFLAMMATORY DISEASES OF BRAIN ARTERIES**

**Infectious Vasculitis**

Inflammatory diseases of the blood vessels of infectious origin and their effects upon the nervous system have been considered in detail in Chap. 32. There it was pointed out that meningovascular syphilis, tuberculous meningitis, fungal meningitis, and the subacute (untreated or partially treated) forms of bacterial meningitis may be accompanied by inflammatory changes and occlusion of the cerebral arteries or veins. Occasionally, in syphilitic, cryptococcal, and tuberculous meningitis, a stroke may be the first clinical sign of meningitis, but more often it develops well after the meningal symptoms are established. The nature of the cerebral vasculitis that may rarely accompany AIDS is unknown.

Typhus, schistosomiasis, mucormycosis, malaria, and trichinosis are rare causes of inflammatory arterial disease, which, unlike the above, is not secondary to meningeal infections. In *typhus and other rickettsial diseases*, capillary and arteriolar changes and peri-vascular inflammatory cells are found in the brain; presumably they are responsible for the seizures, acute psychoses, cerebellar syndromes, and coma characterizing the neurologic disorder in these diseases. The internal carotid artery may be occluded in diabetic patients as part of the orbital and cavernous sinus infections with *mucormycosis*. In *trichinosis*, the cause of the cerebral symptoms has not been established. Parasites have been found in the brain; in one of our patients the cerebral lesions were produced by bland emboli arising in the heart and related to a severe myocarditis. In cerebral malaria, convulsions, coma, and sometimes focal symptoms appear to be due to the blockage of capillaries and precapillaries by masses of parasitized red blood corpuscles. Schistosomiasis may implicate cerebral or spinal arteries. These diseases are discussed further in Chap. 32.

**Noninfectious Inflammatory Diseases of Cranial Arteries**

Included under this heading is a diverse group of arteritides that have little in common except their tendency to involve the cerebral vasculature. One subgroup includes the *giant-cell arteritides*—extracranial (temporal) arteritis; granulomatous arteritis of the brain; and aortic branch arteritis, one form of which is known as Takayasu disease. All are discussed on the following pages.

A second group includes polyarteritis nodosa, the Churg-Strauss type of arteritis, Wegener granulomatosis, systemic lupus erythematosus, Behcet disease, post-zoster arteritis, and AIDS-related arteritis. Immunologic studies have shown that in most of these diseases there is an abnormal deposit of complement-fixing immune complex on the endothelium, leading to inflammation, vascular occlusion, or rupture with hemorrhage. The initial event is thought in some cases to be evoked by a virus, bacterium, or drug. It is postulated by some immunologists that in the *granulomatous arteritides*, a different mechanism is operative—that an
Temporal Arteritis (Giant-Cell Arteritis, Cranial Arteritis; See also page 159) In this disease, not uncommon among elderly persons, arteries of the external carotid system, particularly the temporal branches, are the sites of a subacute granulomatous inflammatory exudate consisting of lymphocytes and other mononuclear cells, neutrophiles leukocytes, and giant cells. The most severely affected parts of the artery usually become thrombosed. The sedimentation rate is characteristically elevated above 80 mm/h and sometimes exceeds 120 mm/h, but a small number of cases occur with values below 50 mm/h.

Headache or head pain is the chief complaint, and there may be severe pain, aching, and stiffness in the proximal muscles of the limbs associated with the markedly elevated sedimentation rate. Thus the clinical picture overlaps that of polyarthritis rheumatica as discussed in Chap. 10. Other less frequent systemic manifestations include fever, anorexia and loss of weight, malaise, anemia, and a mild leukocytosis. Instances of dementia, depression, and other neurologic illnesses that have been described in the literature in patients with temporal arteritis seem to us coincidental.
